The proposal to utilize the motor for ambulance or hospital work is not new. Among those who have given it consideration is Mr. G. H. Colt, assistant surgeon of the Royal Aberdeen Infirmary, who designed in 1910 a portable operating theater to scale, the plan of which he published in the *Journal of Surgery* in 1913. It was not intended for, or designed in reference to, war, which was not then occupying attention, nevertheless the proposal was submitted to the war office and acknowledged. The object in view was to obtain the smallest theater in which an operation could be performed in comfort, to arrange for the contents to be as light as possible, and to mount the body on a chassis of the light car type. Sterilized dressings, towels, gowns, etc., were to be sent on before starting, otherwise the theater was complete. This plan, carried out on a somewhat heavier scale with some slight changes, can be adapted to the war theater and can be taken along the same roads as motor omnibuses or other vehicles. The light or original peace plan is also likely to be of great value at the front where numbers may well be called for.

Prizes of £1,000, £500 and other sums are being offered for the best designs for a motor ambulance body or for improvements in motor field ambulances. The committee or commission for judging owes its origin to Mr. Welcome and consists of representatives of the naval and military medical services and the St. John's Ambulance; Lord Montague, Professor Dalby, and Mr. Robertson are also members, with Dr. Andrew Balfour as treasurer, Sir F. Treves, chairman, and Mr. O'Grady, secretary (10 Harrietta Street, Cavendish Square). The object is stated to be to produce a standard pattern body of perfect design which shall fit standard chassis. Apart from the prizes no payment will be made for designs which the commission may, if it thinks proper, publish for use in the cause of humanity.

The motor bicycle ambulance is already at work. It is a motor bicycle fitted with an ambulance as a side car. The Tyneside doctors have tested one and the Red Cross Society has approved it. It takes two patients lying down on regulation army stretchers. The driver is necessarily occupied all the time with his machine and can give no attention to the traveler. It is, therefore, only available for those wounded who do not require any attention.

London's long-promised service of motor ambulances, we are now told, will not be delayed much longer; managements being nearly complete for starting half a dozen stations under the Act of 1909. The County Council has evidently taken its time, so we may hope that when established its service will lack nothing.

Newcastle-on-Tyne was last week endowed with a perfectly equipped motor ambulance by its medical residents; it was formally presented to the Northern Hospital, the commandant of which in accepting it said it would assuredly prove most beneficial to the patients who were constantly being brought to the hospital.

MEDICAL WAR NOTES.

ELECTRICAL STERILIZATION—THE COOLIDGE X-RAY TUBE—A BULLET LOCALIZER—BREAKDOWNS FROM TRENCH FIGHTING.

LONDON, January 15, 1915.

THE use of electricity in medicine and surgery has rapidly increased during the war, and the busy brains of inventors everywhere have devised means of utilizing methods that were in their infancy not many months ago. One of the most useful applications of a well known electro-chemical procedure described by the writer and by Drs. Beard and Rockwell in the early seventies is ionization, especially of wounds. It consists in the forcing of a metallic salt into the wound-track by means of an electric current so that there shall be an even and efficient coating of an antiseptic. A 1 per cent. solution of zinc chloride is ordinarily used, one electrode being placed upon the chest or in some remote place, and the other in the solution in which the wounded part is submerged. The resistance of the injured tissues involved is much less than the unbroken skin and the consequence is that the path of the bullet is treated to a complete application of the substance. "In ten minutes," says our observer, "a degree of sterilization of the wound may be obtained greater than that produced by continuous days of soaking in ordinary antiseptic baths." This is but a new adaptation of the method that has for some time been in use in England for the treatment of chronic sinuses and other intractable conditions.

The new form of *x*-ray tube invented by Dr. Wm.

D. Coolidge in which the anti-cathode is constructed of tungsten is in use in the military hospitals here. Its superiority to the old tubes is due to the higher melting point, lower vapor pressure, and greater heat conductivity, and there is a marked increase in the intensity of the *x*-rays produced. It has great penetration and the operator may do all his work with a single tube. It is said that a tube has been run for fifty minutes without any adjustment, while the ordinary tube cannot be used for more than a few seconds without showing some material change in penetration. It adapts itself to all kinds of Röntgenographic work, and is taking the place of radium as a therapeutic measure. Mr. Luke Hope, M. R. C. S., who is radiographer at Sir Henry Norman's hospital at Wimereux, has invented a "localizer" which enables him to say that a bullet is at a definite point—so many centimeters below a mark made on the skin—and all the surgeon has to do is to cut down to the indicated depth. It supersedes stereoptic pictures, stretched cords, or elaborate calculations.

Stories of nervous breakdown at the front are familiar, and absolutely used up men are coming back daily to be invalided or retired. These examples include young men some of whom went to the front two months ago in fine physical condition fresh from the football field, but to-day are prematurely old men. This is all due to trench fighting.

4. Lymphatic Leucemia in Acute Infection, after Removal of the Spleen. J. M. Jackson and W. D. Smith.
5. Submucous Resection as a Means of Obliterating Superficial Blood-Vessels. J. Frenn.

1. Scholarship in Medicine.—Theobald Smith states that to sit still in a room, to study, and to think, are the necessary antecedents of the scholar. There is one function of the scholar which should be cherished above all others, namely, to discover and tell the truth. His rewards will always be small. The scholar in medicine must be more than fundamentally serviceable as a part of a great machine. He must be in touch with all its parts.

2. Normal-Looking Brains in Psychopathic Subjects.—E. E. Southard and M. M. Canavan present the results of a study of 153 brains removed at autopsy at the Boston State Hospital. Among these there were twenty brains of a normal appearance. Some of the lesions in the abnormal brains may have had little or nothing to do with the mental disease which their bearers showed. The search for functional psychosis which shall be above all neuropathological reproach is an exceedingly elusive task and possibly never to be rewarded.

3. Emergencies of Extrauterine Pregnancy.—E. B. Young has made a study of 215 cases diagnosed as extrauterine pregnancy, but deals only with sixty-two real emergencies which presented the symptoms accompanying ruptured ectopic gestation with severe hemorrhage. These sixty-two emergencies comprise thirty-one with a previous history, and symptoms typical of ectopic gestation; and yet in many of these the microscope revealed no sign of pregnancy in the tissues examined. As they presented, however, such objective symptoms as shock, tubar rupture, and severe intra-abdominal hemorrhage, there can be little doubt as to causation. Under any circumstances, the indications as to treatment were identical, and hence they have been included. Among these sixty-two emergencies were two coincident extrauterine and intrauterine pregnancies, two repeated extrauterine pregnancies, and one twin pregnancy in a single tube. Exactly 50 per cent. of the patients gave positive evidence of pregnancy. About one-half of the series presented evidences of previous infection of the genital tract.

4. Lymphatic Leucemia Following Splenectomy.—J. M. Jackson and W. D. Smith report the case of a man, aged twenty-one years, who a few weeks after removal of the spleen in 1909 showed an essentially normal blood picture. In 1913 he developed what seemed clinically an acute tonsillar infection; this was quickly followed by marked enlargement of the glands of the neck and moderate general glandular enlargement involving the axillary, inguinal, and epitrochlear glands. This situation was accompanied by a blood picture so typically that of lymphatic leucemia that no other diagnosis seemed possible. After a week of sore-throat, general malaise and moderate elevation of temperature the symptoms abated and a normal convalescence as from an acute infection ensued. Blood examinations done from time to time showed a gradual diminution in the white count and a change in the blood picture from that of a typical lymphatic leucemia on June 3, 1913, to an approximately normal picture on August 23, 1913, and a normal picture on April 15, 1914.

2. Intercostal Thoracotomy in Empyema. — Howard Lilienthal describes an original method of treating empyema as follows: With the patient under nitrous-oxide and oxygen anesthesia a long intercostal incision is made, beginning at a point just outside the costal angle and continuing for the length of the bony rib. A part of the latissimus dorsi and serratus magnus must be divided. This incision throughout its entire length should enter the pleural cavity. With blunt retractors the ribs are now separated until the blades of a rib spreader can be inserted. In working upon the left side the forced retraction must be carried out cautiously, while the operator observes by sight and touch the region of the pericardium. It is conceivable that this membrane, covered by thick plastic exudate, may be ruptured by too violent stretching. When wide retraction has been accomplished and the chest emptied of fluid, systematic inspection of the lung should be made with a view to determine, if possible, the site and character of the focus of infection. A minute point of gangrene, a small bronchiectatic abscess, a sign of traumatism perhaps inflicted by the aspirating needle, or the presence of a broken-down tumor should be dealt with as occasion seems to demand. The entire hand being introduced into the adult thoracic cavity, adhesions may be broken down and lymph coagula removed. With the retraction in the adult of, say, from four to seven inches, perfect visual exploration is now possible. In children the opening, though smaller, will be found ample for exact manipulation. When satisfactory expansion has

been secured and the intrathoracic work has been finished, the rib spreader may be removed and the chest permitted to assume its normal shape. It will be found that the ribs come together nicely, but that on account of the division of such a large part of the intercostal muscles the bones are not as firmly drawn together as when the incision is shorter. Two or three short drainage tubes, carefully secured so that they cannot slip within the chest, are now put in, and it will be found that they are not obstructed by rib pressure. A few interrupted sutures through the skin will close the long wound sufficiently, one or two additional sutures helping to approximate the divided latissimus dorsi. A thick dry dressing is now applied and the patient sent back to bed. Breathing exercises and especially blowing exercises are to be commenced almost immediately. If one is dealing with a simple pneumococcus case uncomplicated by unresolved pneumonia, one may hope for a complete closure of the wound in two weeks. At no time should irrigation be practised. In the complicated cases and especially in the metastatic empyemas, revision may be required. If so, it is merely necessary to reopen the wound and again separate the ribs with the spreader far enough to permit exploration of the suppurating cavity.

4. **The "Auscultoplectrum."** — L. Kolipinski applies this term to an instrument which he has devised to take the place of the ordinary stethoscope, and when combined with a percussion hammer to serve the purpose of a double instrument for both ausculation and percussion. It resembles a monaural stethoscope and consists of the following parts: A funnel end consisting of an Otis urethroscope, size 25 or 26 French scale, with the obturator removed, heavily gold plated; forty-one inches or 104 centimeters of red or black rubber tubing, five millimeters in diameter; an ear piece, and a small, acorn-shaped piece of hard rubber, such as is used in a phonendoscope or binaural stethoscope. The length of the whole instrument is forty-five inches.

9. **Syncope and Fatal Asphyxia under Nitrous-Oxide-Oxygen.**—H. C. Luke reports two cases each illustrating one of these accidents. The fatal asphyxia occurred in a man aged seventy-one years who was operated upon for gangrene resulting from arteriosclerosis. The patient was started on a bag of pure gas with a small supply of oxygen introduced after the first two or three breaths. A moderate cyanosis developed after one minute, becoming more intense and accompanied with a somewhat labored and slowed respiratory effort. More oxygen was then supplied and the gas was shut off, but after a few convulsive efforts respirations ceased and the pupils dilated. In spite of the use of the pulmotor and other methods of respiratory stimulations, death occurred about seven minutes after the beginning of anesthesia. This case tends to confirm the opinion that cyanosis is the cardinal symptom of danger. The second case was that of a woman aged thirty-three years undergoing a radical operation for carcinoma of the breast. During the course of anesthesia a marked pallor rapidly made its appearance, immediately followed by a slight cyanosis, the latter not readily yielding to the extra oxygen supply furnished to correct it. The pupils became moderately dilated, having a sluggish reflex. Respirations were shallow, but not labored. Pulse remained rapid and intermittent. The nitrous oxide was turned off, a large amount of oxygen supplied, and a fairly strong vapor of ether run into the mask with the object of obtaining a quick stimulation of the respiratory center and heart. After a few moments the respirations became much more efficient, with a coincident improvement in the color; the pulse dropped to 104, while the intermittency had practically disappeared and the tension was much improved. The clinical picture here was quite different from the first case reported, there being but slight cyanosis with acute and marked pallor, which was apparently symptomatic of temporary heart failure, together with shallow respiratory effort from the general prostration; on the other hand, in the fatal case, cyanosis and labored breathing were the predominant symptoms, with complete heart failure supervening as a secondary result.

3. **Ankylosis.**—N. Allison and B. Brooks conclude from their experiments that any inflammatory process within a joint which is of sufficient severity to result in the formation of granulation tissue will destroy the joint cartilages. The cartilage is absorbed at its margin by granulation tissue arising from the synovial membrance and at its base by granulation tissue from the bone marrow. By the experiments in which the cartilage was removed by operation, or the point partially excised the authors have shown that ankylosis by bone is a slowly developing process which consists of the following stages: (1) There is union by granulation tissue: (2) there is union by dense fibrous tissue, and (3) there is a metaplasia of fibrous tissue into cartilage and a direct transformation into bone. The shortest period of time in which complete bony ankylosis was observed experimentally was 180 days. In man the duration of the process is equally prolonged. The long duration of the process of osseous ankylosis explains the following: After arthroplasty a joint may allow motion for some weeks and subsequently become stiff. Fractures of the epiphysis unite by bone slowly. It also suggests that the conclusion reached by certain investigators that the interposition of soft parts prevents bony ankylosis is misleading in that many of their experiments were of insufficient duration. The long duration of the fibrous stage of ankylosis also shows conclusively that any method of arthroplasty should have as its object the prevention of fibrous ankylosis rather than bony ankylosis, also that the insertion of an irritative substance into a joint should be avoided.

4. **The Blood Pressure During Pregnancy.**—F. S. Newell points out that a considerable number of patients

have a temporary rise in blood pressure during pregnancy without the development of other symptoms, as is found in patients under other conditions. The significance of this rise in blood pressure can be ascertained only by a frequent study of the blood pressure in a large number of cases. In other cases studied by the author the rise in blood pressure was followed by the appearance of albumin, a combination which has been shown to be a definite indication of the development of toxemia. In only one case, however, did convulsions develop, the other cases yielding to treatment. Thirty-nine cases showed slight traces of albumin in the urine, but no changes in the blood-pressure. As the urine was not obtained by catheter, the source of the albumin is unknown, but in the majority of the cases it was probably due to contamination of the urine by leucorrheal discharge. To judge from these cases, the presence of a slight amount of albumin, if not accompanied by a rise in blood pressure, is negligible. Eleven patients showed albumin with a high blood pressure, all of these being presumably more or less toxemic. Five patients showed a blood pressure of 140 or over throughout the period during which they were under observation. Only one of these patients developed albumin at any time during the pregnancy, and all passed through labor normally, which would tend to prove that persistent high blood pressure, in the absence of other signs, is not necessarily a dangerous symptom, although it should always arouse suspicion and call for increased watchfulness, whereas, as was shown in other cases in this series, a rise in blood pressure from a low point is not infrequently followed by the appearance of albumin and the development of symptoms of toxemia, and is more significant than a high pressure throughout.

5. **Hypopituitarism in Chronic Hydrocephalus.**—L. J. Pollock calls attention to the frequency of the association of hypopituitarism with hydrocephalus. The similarity of serous meningitis to tumor cerebri is well known, and the inclusion of pituitary symptoms may lead to a diagnosis of tumor of the hypophysis wrongly. The involvement of the pineal gland in the mechanical injury resulting from a cystic third ventricle deserves further study in its relation to cerebral adiposity.

7. **Bone Transplantation in Potts' Disease.**—C. M. Jacobs finds that: (1) surgical measures for tuberculous spine disease are a great advance over conservative treatment but should be restricted to selected cases; they shorten the period of disability. (2) Not only may existing deformity be prevented from becoming exaggerated, but also deformity itself may be prevented by surgical measures. (3) Too early reliance cannot be placed on the strength of the bone graft; it takes time for the splint to become securely fixed by permanent callus. (4) External support must not be disregarded for many months following the operation; otherwise deformity may ultimately occur. (5) Even with postoperative protective treatment for a period of six or more months, the duration of treatment is much shorter than the average duration under nonoperative methods. (6) The success of bone transplantation for the cure of tuberculous spine disease depends on the proper implantation of the bone splint into the diseased and normal contiguous vertebræ. Essential to the success is the careful protective after-treatment for a period of months.

2. **The Pigmented Appendix.**—W. H. Battle reports two cases of marked pigmentation of the appendix met with in women. He has already reported four similar cases. In every instance after removal of the appendix for disease, examination of this structure revealed that it was the seat of an extensive brownish-black pigmentation evidently not limited to the appendix but spreading an unknown distance into the large bowel. The patients were all of the female sex, and in each there was a history of constipation of long standing, which amounted to intestinal stasis in more than one of them according to their medical attendants. It would appear as if in some the difficulty with the bowels had led to a secondary inflammatory affection of the appendix. Operation in each was for the relief of pain caused by this. The pigmentation was found on examination of the removed appendix, and in only one was there any appearance of darkening of the bowel as examined from the operation incision. Microscopical examination showed the deposit to be both in and between the cells of the mucous membrane. Chemical analysis of the first three specimens showed that the pigmentation was produced by a deposit of iron, the exact combination not being defined owing to the small quantity of material available. The author believes that the source of the iron is wheat flour which contains a small quantity of iron derived from the iron rollers used in the modern process of milling.

3. **The Salicylates in Rheumatic Infection.**—R. Miller states that the theory that salicylates have the power of diminishing the activity of the rheumatic infecting agent may be taken as the working basis of salicylate therapy in rheumatism, and the drugs should be administered with the sole view of controlling the bacterial activity. Of this the temperature chart is as accurate an index in rheumatic as in other infections (*e.g.* tuberculosis). Care must be taken to discriminate between symptoms directly due to active rheumatic inflammatory processes and those dependent upon toxic parenchymatous changes which may remain long after all bacterial activity is at an end. Used solely with a view to controlling bacterial activity, the effective range of dosage for child or adult is usually from 60 to 120 grains per diem. Less than 1 dram daily is rarely sufficient; more than 2 drams need seldom be given. Much larger doses than these have been shown to be safe if properly administered, and if necessary to gain control may be used, but for the most part "massive" doses have been administered in cases of chorea in which there was no evidence of bacterial activity remaining. Any dose greater than 100 grains daily should be given subdivided into 10 doses in the 24 hours. Large infrequent doses should never be given, particularly in children. Constipation must be avoided. The sodium salicylate should be combined with an equal dose of sodium bicarbonate. Vomiting in cases of severe cardiac dilatation may be difficult or impossible to prevent, but in other cases may be avoided for the most part. The more serious symptoms of salicylate poisoning (acid intoxication) should nowadays never be allowed to arise.

4. **Dry-Cupping in Laryngeal Affections.**—W. Stuart-Low extols the use of this procedure for which a special suction apparatus may be employed. He has had cups made of various sizes and shapes for adaptation to the front and sides of the larynx, and has found it best to have the edges of the cups covered with rubber so that any inconvenience the patient might feel when the suction is strongest may be minimized. Some of these cups are half-moon shaped, others horseshoe shaped. Suction can be applied effectively to one or both sides of the larynx simultaneously. There is an

adjusting mechanism on the instrument by which the suction force can be varied from five to one hundred pounds air pressure. The vascularity of the larynx is favorable to the process of dry cupping as the vessels enter and pass out at definite sites. For the most effective relief of vascular and edematous congestion of the interior of the larynx the cups should be applied over the posterior half of the thyrohyoid membrane and over the cricothyroid membrane both laterally and in front. The author cites cases of subglottic laryngitis, laryngeal tuberculosis, and acute laryngitis, in which this measure was promptly effective. He suggests that the treatment may be useful in cases of laryngismus stridulus.

5. **Static Electricity in Medicine and Surgery.**—J. J. Grace summarizes the effects of static electricity as being chiefly mechanical just as those of the constant current are chiefly due to the carriage of ions by the current and those of high frequency are chiefly due to its heating effects. The static current is useful in lumbago, sciatica, and brachial neuritis; in reducing the size of an enlarged prostate; in the treatment of subinvolution of the uterus and dysmenorrhea; in the relief of spasm in muscles connected with inflamed nerves and joints; and in the stimulation of degenerated nerves.

British Medical Journal.

January 23, 1915.

1. Surgical Notes from a Temporary Clearing Hospital at the Front. A. A. Martin.
2. Acidosis and the Nitrogen Partition in Pregnancy. A. Leith Murray.
3. Cases of Inoperable Cancer Treated with Goat Serum. A. Wilson.
4. A Case of Tetanus: Recovery. J. H. Evart.

1. **Notes from a Clearing Hospital.**—A. A. Martin presents a vivid description of some of the methods of modern warfare. It has been said that to-day wounds of eighteenth century character are being treated with twentieth century technique. The eighteenth century battle wounds were inflicted at close range, so are many of the wounds inflicted to-day. At Cressy and Agincourt both sides used arrows; aviators to-day carry sharp arrows, which they spin down on the enemy below. Bombards were used at Cressy, and bombards are used in the trenches to-day. Hand grenades were employed in the Peninsular war, and are employed to-day in the War of the Nations. Men attack the enemy with bayonets, as in the days of the Crimea and the Peninsula. Riflemen pick off the enemy by long distance fire, and also fire at close range into solid masses of them. The hardships of the Crimean trenches—cold and frost-bite—are repeated on the Yser. Gangrene was rampant at one time in the Peninsula amongst the French and British wounded, and it has startlingly reappeared to-day.

2. **Acidosis and the Nitrogen Partition in Pregnancy.**—H. Leith Murray credits Whitredge Williams with the institution of a scientific method of examining the urine in pregnancy. The author describes a number of tests which are easily applicable in the clinical laboratory. As regards the total nitrogen this should be used merely as the total from which to calculate the ammonia percentage. It can have no other reliable value unless the nitrogen values of the food and feces are simultaneously examined. The normal ammonia nitrogen coefficient in the non-pregnant state is 3 to 5 per cent., *i.e.* this percentage of the nitrogen in the urine is eliminated as ammonia. In pregnancy, even in clinically normal pregnancy, these limits may be greatly exceeded. There is a widespread and absolutely unjustifiable belief that this increase of ammonia must necessarily represent and measure an acidosis; but, there is every reason to assign a part of the ammonia (and that perhaps a large one) to the histological changes occurring in the liver. It is certain that primary liver disease—primary disturbance of the protein metabolism—is associated with an increase. In toxic pregnancy increased ammonia is most in evidence in hyperemesis, in which the lesion is essentially a degenerative one, while in eclampsia the predominating lesion is often a massive focal necrosis. Whitredge Williams regards a low ammonia value as a good sign in toxemia vomiting and a bad sign in eclampsia. What, then, the author asks, is the best test that the body is suffering from the condition ordinarily called "acidosis"—that is, a depletion of the fixed bases? It would appear very reasonable to believe that the best test is one of tolerance to alkali. Expressed differently, if the body is in no need of fixed bases, any alkali introduced will be eliminated, and the urine will become alkaline. On the other hand, if there be a need for fixed bases, when alkali is introduced, it will remain in the body, and the recation of the urine will remain unchanged.

3. **Inoperable Cancer Treated with Goat Serum.**—A. Wilson states that J. H. Shaw-Mackenzie has shown that while normal serum in health contains a substance which has the property of activating or accelerating the fat-splitting action of pancreatic juice and pancreatic extracts, in certain cases of cancer this property is considerably increased. In progressive and advanced cases this power of the serum is decreased compared with the action of normal serum examined at the same time as a control, while the normal antitryptic action of the serum is increased in accordance with the original observations of Marcus, Brieger, and Trebing. When these two reactions are present they aid in the diagnosis of cancer, and when they are absent they exclude cancer. During quiescence or improvement or after apparent recovery the accelerating fat-splitting action of the serum is high, while the antitryptic action falls to normal or is subnormal. This accelerating fat-splitting property of the serum is greater in the lower animals than in human serum, while the antitryptic action of the serum is not greater than with normal human serum. Inoculation of animals with normal tissues or with cancer tissue is followed by a similar increase in this property of the blood; while in mice which had been inoculated with mouse tumor and did not "take," and also in mice which had recovered spontaneously from large growths, the accelerating fat-splitting action of the serum is high. In view of such facts Shaw-Mackenzie has suggested that "the fat-splitting acceleration is a possible and natural factor in resistance to disease in carcinoma and in other conditions," and "if so, serum and substances which increase this action or protective mechanism are indicated in treatment." The treatment of inoperable cancer by means of normal goat serum is not empirical, for one is introducing an actuator of the fat-splitting protective action in the tissues. The author reports six cases of inoperable cancer in which either the disease was apparently cured, as in one instance, or life was prolonged, or pain was relieved.

Berliner klinische Wochenschrift.

December 28, 1914.

Injury from Indirect Projectiles.—Melchior, who has already reported a case of injury due to impact of a projectile on a wrist watch furnishes a second example. A Russian grenadier who carried a watch on his left wrist was struck by an ordinary small arm bullet which drove the debris of the watch into the wrist joint. The resulting wound was large and ragged and bled freely. During the fight he was taken prisoner and because of

the severity of the general reaction was transported at once to Breslau. When admitted to Professor Kuttner's clinic he was evidently septic. The left hand and forearm were much swollen, and the wrist joint exposed. The large ill-looking wound had an offensive secretion. The gangrenous thumb with its metacarpal hung loose in the palm. The *x*-ray showed that the bases of the first three metacarpals were comminuted, along with all but two of the carpal bones, and the head of the radius to the right. Metallic splinters could also be seen and a coarser object which proved to be the suspension ring of the watch. All the badly damaged tissues were ablated and broad incisions were made in the forearm in which a gas phlegmon was in evidence. After the intervention the general sepsis disappeared. The limb is of course worthless.

Case of Intoxication Following the Exhibition of Tetanus Serum.—Boenheim reports a case which he does not classify as an anaphylaxis. A patient who had received a prophylactic injection showed a local reaction suggesting primary serum disease. The chief symptom was an intense pruritus at the site of the injection and later over the chest, which prevented sleep. The condition progressed, but seemed much improved after defecation, although at the same time the patient collapsed and showed weakness for a short time. To the pruritus was then added a general urticaria. The suffering could not be alleviated permanently. Fever now set in. On the following day the cutaneous manifestations had disappeared, but violent pains in the muscles, joints, and bones replaced them. The nerves seemed intact. There was also great weakness. Nothing brought relief. The condition gradually wore off. There was nothing about these symptoms to suggest the activity of the antitoxin which has never been known to attack the locomotive system. The most likely explanation is that some heterologous albumin had found its way into the serum as an impurity. Other patients who received the same serum developed slight local itching.

Sepsis with Blood Picture of Aplastic Anemia Following Gonorrhea.—Buschke and Hirschfeld report a case which they sum up as follows: A man aged 25 developed gonorrhea and gonorrheal rheumatism for which he received intensive treatment but showed not the slightest improvement. His general condition became wretched and when interned in a hospital he presented anterior and posterior urethritis and bilateral arthritis of the knee. While under treatment he developed fever, and acute hemorrhagic diathesis and soon succumbed. A high degree of anemia coexisted. The staphylococcus was present in the blood and knee-joints. The autopsy showed further acute nephritis, severest anemia, abscess in the right lung, and a flabby heart. Staphylococci were cultivated from the bone marrow. The starting point of the sepsis was probably a periurethral abscess which contained staphylo- and streptococci.

Münchener medizinische Wochenschrift.

December 22, 1914.

Experience with Vaginal Operations under Parametrian Conduction Anesthesia.—Ruge gives his experience with his first 22 cases of this form of anesthesia, which have already been made the subject of a dissertation by Baltzer. The nearest approach to the author's method consists of injections into the portio or cervix for minor interventions. The author goes much further in search of an anesthesia for hysterectomies, myomectomies (vaginal), fixations, etc. The parametrian anesthesia is effected simply by injecting a sufficient quantity of 1 to 2 per cent. novocain-suprarenin solution with a long needle into each half of the parametrium. The highest point of the fornix is selected, the needle pointing away from the uterus. This instrument should follow the course of the broad ligament, save in the case of a retroflexion or similar displacement. In intact parametrium there is no danger of wounding the veins provided the needle is introduced slowly, but if chronic parametritis is present the author refuses to inject. Simple needle puncture should precede the injection, but following escape of blood does not contraindicate injection; on the contrary the direction of the needle is slightly altered. The uterus and vagina become anesthetized in from 20 to 25 minutes and lasts about 1¼ hours. Of the 22 operations performed 10 were for cancer of the cervix, and the balance was distributed among genital prolapse, metrorrhagia, myoma uteri, old perforation of uterus, carcinoma corporis, vesicofixation and vaginofixation. The anesthesia, Ruge says, was eminently successful in all but one of the cases.

Etiology of Endocarditis Verrucosa.—Reye, speaking of the benign form, states that it may develop in connection with the most varied infections and cachectic affections. A problem for solution is the nature of the lesion—how far bacterial and how far toxic. No one microorganism has ever been brought into etiological relationship with all these affections; but the great number of species found in the lesions is very suggestive. As far as Poynton and Paine are concerned, they have gone on record in the belief that a unique cause is responsible for rheumatic infections in the narrower sense. These causes are microorganisms partaking respectively of the qualities of the strepto- and diplococci. This diplococcus is found alone in the more malignant cases. The author has been at work on this problem since 1913. His results will be summarized in the next number of the *Wochenschrift*. An extensive discussion is also published.

Tuberculosis and Warfare.—Liebe states that the outbreak of the war has raised several questions in connection with the warfare against tuberculosis which can be readily surmised. In the first place the campaign against the disease could readily be disturbed. Again workmen thrown out of employment may be conceived of as using this forced idleness for the treatment of threatened tuberculosis. Still again the war is bound to arouse much latent tuberculosis, and this also applies to war prisoners. The general result is a stampede toward the sanatoria which cannot begin to accommodate the war material. The latter should have temporary shelters. There should be experts in tuberculosis at the front to isolate victims of the disease. At the beginning of the war various sanatoria were commandeered for military hospitals, and these, Liebe says, could certainly be utilized for the care of tuberculous soldiers.

Status Lymphaticus.—Hugo Pribram has studied a large number of cases of this condition and has found that none of the large number of physical changes attributed to it is by itself characteristic. The distance between the extremities of the outstretched arms exceeds the body length in 95 per cent. of the cases. Instead of the blood pressure being constantly diminished, as is alleged, it was normal in one-half of the cases. On the other hand considerable importance must be attached to the hypertrophy of the papillæ at the base of the tongue and to the infantile or omega conformation of the epiglottis. Lymphocytosis is frequently present; and sometimes, particularly in cases of genital hypoplasia, eosinophilia and basophilia are present.—*Zeitschrift für klinische Medizin.*

Insurance Medicine.

Medical Section of the American Life Convention.—At the fifth mid-year meeting of this society, to be held at French Lick, Ind., on March 3-5, the following program will be presented: "From the Outside Looking In," by Hon. Charles A. Bookwalter, Indianapolis; "Goiter and Life Expectancy," by Dr. Charles H. Mayo, Rochester, Minn.; "Life Insurance and the Kidneys," by Dr. J. S. Lankford, San Antonio, Texas; "The Five Senses in Life Insurance," by Dr. W. A. Peterson, Chicago; "Medical Frauds," by Dr. Albert Seaton, Indianapolis; "The Appointment and Management of Local Examiners," by Dr. J. H. Florence, Houston, Texas; "The Business Organization of the Medical Department," by Dr. Henry Wiseman Cook, Minneapolis; "The Scope and Function of the Medical Department," by Mr. Charles F. Coffin, Indianapolis; "Hypertension as an Impairment," by Dr. M. L. Turner, Des Moines, Iowa; "One Method of Life Conservation," by Dr. H. R. Allen, Indianapolis; "Policy Holders as a Medium for Increasing Longevity," by Dr. W. K. Blackford, Louisville, Ky.; "The Medical Referee," by Dr. D. W. Layman, New York; "Operations on the Gall-Bladder in Relation to Life Expectancy," by Dr. W. S. Harpole, Chicago; "Post-Operative Risks," by Dr. H. N. Mayo, Salt Lake City; "Pellagra and Hookworm Disease in Relation to Life Insurance," by Dr. N. J. White, U. S. Public Health Service. The officers of the section are: Dr. Whitfield Harral, chairman; Dr. F. W. Foxworthy, vice-chairman; Dr. F. L. B. Jenney, secretary.

The Medical Directors of Texas Life Insurance Companies held their annual meeting in Waco on January 12, at the same time as the Central Texas Medical Society, under the presidency of Dr. W. A. King of San Antonio. Dr. William M. Brumby of Waco was elected president and Dr. M. M. Smith of Dallas, secretary-treasurer.

Some Danger Signals in Life Insurance Examinations.—Not long ago a prominent insurance company was called upon to pay a very large amount of money on the policies of two men who had been recently insured. The papers seemed to be correct, yet there was evidence that in some way the medical examiner had failed to recognize the character of the risks, and to forecast the early and almost certain death of the policyholders. The applicant often presents no general symptoms from which to anticipate other than the average life and longevity, yet a little closer acquaintance and study brings out some facts that are certain to materialize and change the future. Dr. T. D. Crothers says that the examiner is really a high-class detective in insurance work, for it is his province to determine the facts and their meaning, then give the scientific significance of the conditions relating to longevity and the danger of mortality. Alcohol, used either in moderation or excess, as an active agent in disease favoring mortality, exceeds any other known agent. These facts have grown out of statistical studies, and are not dependent on personal opinions or theories. The reports of three British life insurance companies covering a period of nearly twenty years shows that those who were insured as moderate or occasional drinkers had 50 per cent. higher death rates than those insured as total abstainers. In one of the companies two sections were made, one of total abstainers which showed 39 per cent. greater mortality than in the one composed of occasional or moderate drinkers. Another company reported 10,000 deaths of total abstainers and 14,000 deaths among the occasional drinkers, covering a period of twenty-five years. These figures show that one of the greatest perils to life companies is losses due to spirits and drug taking. It is the medical examiner who must be able to read and interpret the danger signals which point to early mortality, irrespective of any physical signs of the present. The neurotic history, habits of work and living, and mental health and integrity of the applicant are influential factors from which to determine his future. Between the muscle and the brain worker, the former is a better risk than the latter, conceding that they both live irregular and unhygienic lives. The exact condition of the heart, digestion, kidneys, and other organs is of minor importance compared with the efforts to conserve and repair the exhausted energies. A very active business man carrying great responsibilities, who is negligent and careless of the ordinary rules of hygienic living, who may be an abstainer as far as spirits are concerned, but consumes irregular quantities of food, drinks coffee and tea excessively, and uses tobacco freely, is a bad risk no matter how negative all the other symptoms may be. Business men whose diet is irregular and who fail to exercise properly and neglect to rest are wearing out rapidly. They are continually drawing on the vital resources with no time for restoration and repair. There are many persons, in both professional and business life, between the ages of thirty and fifty, who are active, successful men with constantly increasing responsibilities, whose futures and prospects are continually brightening. The ordinary physical examination would be called practically negative. The family history is usually good. They may use wine, beer, or spirits, most often do; eat heavily and irregularly; show no care of their bodies, and may be careless in hygienic matters. There are two mental conditions prominent among these active brain workers that should always be regarded with significance. One is extreme optimism and egoism with extraordinary confidence in one's own strength and ability. This should always excite attention, and suggest toxic poisonings, central nerve changes, especially when associated with an irritable heart and high-tensioned arteries. It makes the forecast for the future ominous. The other is that of pessimism, despair, suspicion, and doubt. Often these conditions are the only signs of ill health and low vitality. These are danger signals that the examiner should report. Longevity and disease are very largely influenced by diet and correct habits of living. The meat eater, who believes that only meat will give strength, and the vegetarian, should both be studied, particularly if they are actively engaged in the affairs of life. Every applicant for large policies should submit to frequent examinations and counsel concerning his mode of living and conduct. The examiner should be really a health officer, not only to protect the company, but to lengthen out the life of the individual by diminishing the possibility of disease. Every applicant should be considered from both the psychic and the physical aspect, in order that many of the danger signals, now unread and unheeded, may be used as sign-posts of protection to both the individual and the company.—*Medical Review of Reviews*, October, 1914.

Book Reviews.

A Text-Book of Pathology. With a final Section on Postmortem Examinations and the Methods of Preserving and Examining Dead Tissues. By Francis Delafield, M.D., LL.D., Emeritus Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, New York, and T. Mitchell Prudden, M.D., LL.D., Emeritius Professor of Pathology, College of Physicians and Surgeons, Columbia University, New York. Tenth edition. Revised with the coöperation of Francis Carter Wood, M.D., Director of Cancer Research, Columbia University, New York. With fourteen full-page plates and six hundred and ninety-four illustrations in the text, in black and colors. Price, $6.00 net. New York: William Wood and Company, 1914.

This new edition of Delafield and Prudden—the tenth—retains all of those admirable features which have made the work the most popular text-book on pathology in English. Despite the fact that the size of the volume has been but slightly increased, many changes and additions are to be found, and these, with the insertion of a number of new cuts, greatly increase the value of the work. The reviewer notes especially additions in the section on tumors, necessitated by the experimental studies of the last few years, a revision of the section on the transplantation of tumors and acquired immunity to these growths, a new section on the transplantation and *in vitro* growth of tissues, changes in the classification of parasites, a good summing up of the recent advances in our knowledge of the widespread occurrence of the fungus of the genus Sporotrichum and its pathogenic rôle in the production of chronic granulomatous lesions, and a new section on pellagra, an earnest of the importance which this protean disease has reached in the United States. The tissue changes following the action of *x*-rays and radium are reviewed, and an entirely new section on exophthalmic goiter, with an extremely useful plate of photomicrographs showing the various lesions found in the thyroid in this disease, has been added. The recent investigations on poliomyelitis are included and a considerable number of changes have been made in the chapter on technique. Throughout the volume the references have been amplified, that portion of the bibliography which has become somewhat antiquated being omitted and more recent articles, especially those which contain comprehensive reviews, being inserted. The authors have again wisely avoided any attempt to make the volume a mere disjointed encyclopedia of separate chapters, and it still retains the great advantages which appertain to a work composed by one person, in the correlation of the subject matter, and the lack of repetition so often painfully obvious in compilations in which each chapter is taken by a different writer. The title page shows that Prof. F. C. Wood has been added as an active collaborator in the revision of this valuable text-book, which has for so long been a standard work in pathology.

Infection and Resistance. An Exposition of the Biological Phenomena Underlying the Occurrence of Infection and the Recovery of the Animal Body from Infectious Disease. By Hans Zinsser, M.D., Professor of Bacteriology at the College of Physicians and Surgeons, Columbia University, New York. Formerly Professor of Bacteriology and Immunity at Stanford University, California. With a chapter on Colloids and Colloidal Reactions by Professor Stewart W. Young, Department of Chemistry, Stanford University. Price, $3.50. New York: The Macmillan Company, 1914.

The need of a book covering all the phases of the recent discoveries in immunity and infection has been felt for some time. Metchnikoff's classic work is now completely out of date, and some of the recent summaries have been ill-digested and imperfect, while the volumes of studies of the Ehrlich school and those of Bordet are merely series of isolated research articles bound together by a very thin thread of relationship. For these reasons the volume under consideration is most welcome, and the more as it fulfills all requirements in a fashion which can be described only as admirable. The author's experience as a practical teacher of the phenomena of immunity leads him to appreciate the difficulties with which the student meets in studying the original papers of those who have done so much to develop our knowledge of this subject in the past twenty years. To such a student this book will prove an illuminating guide, though perhaps not the easy reading that he may hope for; the complexity of the subject forbids that. The writer's training gives a value and point to the illustrative examples which are refreshing. The fact, also, that he has been an investigator in many of the phases of the work of which he writes lends an authoritative quality to every statement. The volume opens with a brief but admirable survey of infection and the problem of virulence. Then follow chapters on natural and acquired immunity, while subsequently the phenomena following immunization are considered. There is an excellent résumé of the Ehrlich hypothesis—that theoretical scaffolding which has been so useful because of its simplicity in stimulating further work, though so dangerous because of Ehrlich's fatal capacity of giving attractive names to substances and processes of which we know but little and thereby creating an impression of finality which does not exist. It is evident, however, that the writer has many sympathies with the views of the French students of immunity, and he wisely points out where the diversity of opinion has been a wholesome restraint on cocksure statements. The criticisms by Arrhenius and Madsen of the Ehrlich hypothesis are also given their due weight. In that most complex and difficult of subjects, anaphylaxis, the writer is especially at home for much of his own research has been along this line. The time is apparently not yet ready for a final explanation and evaluation of the anaphylactic phenomena. So many seemingly contradictory observations have been published in this field that it is difficult to reconcile them in a consistent summary, and yet, as far as possible, this has been done. It is interesting to note that the writer doubts that any non-protein substance may act in the production of anaphylaxis. A chapter which is especially to be commended is that on the clinical significance of anaphylaxis, and this and the final one on therapeutic immunization in man may be read with profit by every physician. The Abderhalden and meiostagmin reactions are reviewed in sufficient detail. Professor S. W. Young has added a final chapter on colloids. Undoubtedly future work in this complex and difficult borderland will cast much light on the obscure reactions which we see in immunity; and inasmuch as a large part of the work can be done with inorganic substances and in quantitative fashion the advances may be more rapid here than by the direct study of immune phenomena. In conclusion, it must be said that the volume is written in an admirably free and clear style, that the author does not hesitate to state when our knowledge is contradictory, and that all the important observations have been included in the text. It will render superfluous many of the older works on immunity, and it is difficult to see how a better and more instructive volume can be produced in the near future. The publisher's part of the work is good, the paper is light with a good surface, the size of the page and type is excellent, and the illustrations while extremely diagrammatic are perfectly satisfactory. A very complete bibliography has been added, and the only real criticism which can be offered is that in it, as a rule, only the year and volume references are given, seldom the number of the page. In a future edition the references should be made complete, so as to avoid the necessity of searching through a volume, and so that in case a misprint occurs much vain hunting for a paper can be saved. The index, so far as it is possible to verify it, is good, and but few misprints have been noted. The writer is to be congratulated on the production of an admirable book which should be a classic for many years to come.

The Clinics of John B. Murphy, M.D. Vol. III, No. 4. Octavo of 254 pages, with 65 illustrations. Published bi-monthly. Price per year, paper, $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1914.

The opening article in this issue is a discussion of ileus, in which Murphy brings out the point that ileus is not a pathological entity, but a syndrome. Other subjects in which diagnostic points are particularly dwelt upon are a discussion of the relations of uterine tumors to menstrual flow, malignant papillomatous cyst of the breast, and cerebellar tumor, this latter with discussion of neurological symptoms by Dr. Mix A large part of the balance of the volume is taken up with the almost inevitable bone and joint cases, including arthroplasties, nailing of old ununited Colles' fracture after open reduction, sarcoma of the humerus, luxations of the patella and arthrodesis for a flail joint.

Society Reports.

CLINICAL CONGRESS FOR THE STUDY OF LOCAL, SPINAL, AND SCOPOLAMINE MORPHINE ANESTHESIA.

This Congress Was Held Under the Auspices of the Chicago Medical Society, January 26, 27, and 28, 1915.

DR. BERTHA VAN HOOSEN, IN THE CHAIR.

Spinal Anesthesia in General Surgery. — Dr. W. WAYNE BABCOCK of Philadelphia, had done one craniotomy successfully upon a child under local anesthesia, resecting the scalp, and the child sat up to have the bandage applied. He had also done the following operations under this form of anesthesia: 2 rhinoplasties, several mastoid operations, several operations upon the upper extremities, 14 operations upon the breast, 25 operations upon the ribs, such as thoracotomies, and one anterior mediastinotomy. In one patient on whom he attempted to resect the lower jaw and succeeded, there was sudden collapse, requiring twenty minutes to resuscitate the patient. Two patients in whom he resected the ribs for empyema, with pulmonary involvement of the other side suddenly collapsed, but as soon as the fluid was withdrawn the heart action was restored in both instances. He had limited spinal anesthesia to operations below the diaphragm. In the upper abdomen he had done 152 operations involving the stomach; 2 of these were complete gastrectomies, 29 were partial gastrectomies, 33 gastroenterostomies, and 30 were done for perforative ulcers. In three of these it was necessary to resect a part of the pancreas on account of involvement from carcinoma. In two additional patients with advanced cancer he found they were in such bad shape as to make it unsafe to do resection of the stomach. There were no deaths in this series. Spinal anesthesia should be limited to patients in fair condition. In debilitated patients with advanced cancer of the stomach his present plan was to use local anesthesia, and in this class with thin walls one could often do a resection of the stomach with a fair degree of facility rather than use spinal anesthesia. On the biliary system he had performed 261 operations, 95 cholecystotomies, and 104 cholecystectomies. In patients exceedingly toxic and greatly weakened it was safer to use local anesthesia because usually only drainage of the gall-bladder was required with the possible removal of stones. In patients with high peritonitis, who had weak hearts, spinal anesthesia constituted a distinct danger. He had performed seven splenectomies. In these there was no trouble. In one patient the spleen weighed 13½ pounds. For kidney and ureteral surgery spinal anesthesia was exceedingly useful. Upon the bladder, ureter and external genitals he had performed 219 operations under spinal anesthesia with satisfactory results. Upon the intestines he had done 114 operations, 31 of which consisted of complete resection of from a few inches up to 16½ feet. Upon the abdominal wall he had performed 84 operations, of which 36 were lipectomies. There had been 746 herniotomies done; between 80 and 90 of these were done for strangulation in various parts of the abdominal wall. Of amputations he had had 78; he had had 159 operations upon bones and joints, 87 upon veins, 21 upon nerves, and 9 upon the spine. After ether 50 per cent. of the patients complained of headache; after spinal analgesia 21 per cent. The headaches from ether were more intense than those from spinal anesthesia. Spinal analgesia insured physical quietude on part of the patient before and after operation. Under spinal anesthesia there was complete muscular relaxation. This meant much to the operator.

Spinal Anesthesia in Gynecology.—Dr. HERMAN J. BOLDT of New York City, stated that spinal anesthesia had many adherents, but more opponents. Of 1,000 cases in which novocaine was used he had failed to find a single reported fatality that could be attributed directly or indirectly to the drug, and for this reason he began to use spinal anesthesia. He had had one complete failure, and two partial failures, making the use of a small quantity of ether necessary. Nausea and vomiting were disagreeable in abdominal operations, but these seldom occurred under spinal anesthesia. He would not care to subject any patient to spinal anesthesia without preliminary narcosis, so that the patient would be utterly oblivious of his or her surroundings. Lastly, he would sooner give up the use of the scalpel in doing surgery than to give up spinal and local anesthesia in connection with preliminary narcosis by morphine and scopolamine.

Sacral Anesthesia (Extradural Injection of Cocaine) as Used in the Freiburg Frauen Clinic.—Dr. KURT E. SCHLOESSINGK of Freiburg, Germany, stated that up to the year 1912 the record of the Freiburg Clinic was 2542 cases of spinal anesthesia without a single death or a single case of paralysis of respiration. He did not think the choice of the anesthetic itself was of such great importance. Stovaine and novocaine were equally effective. The most important things for the success of the anesthesia were the amount, the specific gravity of the solution, the freezing point of the solution, the temperature of the solution at the moment of injection, and the position of the patient during and immediately after the injection. High extradural anesthesia should not be used in cases of pregnancy and abdominal tumors. Sacral anesthesia should not be used on obese women because of the difficulty of finding entrance for the injection. The most pleasant feature of sacral anesthesia was the absence of after effects. Postoperative vomiting rarely occurred, and this was important in operations upon the stomach and intestines. Technique of these methods of anesthesia demanded a number of trained assistants.

Spinal Anesthesia as Used in South America.—Professor DEBAYE of the University of Nicaragua had used spinal anesthesia in hundreds of cases of various operations, and thus far had not had a death. He had observed headache and vomiting in a few cases, and in two instances suboccipital pain which lasted for six or seven days. We should avoid the use of irritant drugs. Concentrated solutions should be used and strict asepsis observed. We should never choose an interspace above the eleventh dorsal for the injection, and the injection should be made with care. The heavier solution should be used when the patient is in a sitting posture, and with the use of the light solution the patient should be made to lie down after the injection. He had done several suprapubic sections for the removal of tumors, vaginal hysterectomies, abdominal hysterectomies, nephrotomies, etc., under spinal anesthesia with satisfactory results.

Dr. DAVID C. STRAUS of Chicago said he had used sacral anesthesia in fifteen or twenty cases of hemorrhoids, and when the solution was fresh he was able to secure perfect anesthesia. Muscular relaxation was complete. Cardiac cases were not suitable for sacral anesthesia. In pulmonary and renal cases sacral anesthesia was highly contraindicated.

Cesarean Section under Local Anesthesia.—Dr. J. CLARENCE WEBSTER stated that about ten years ago he began to use Schleich solution No. 2 for cesarean section in the Presbyterian Hospital, using it only for vaginal cesarean section, the cases being those in which that operation was considered advisable, namely, those of rigid cervix or of hypertrophic elongation, with eclamptic phenomena. He was pleased with the results and operated over twenty times vaginally with a local anesthetic. Then he extended the use of Schleich solution to other operative procedures. For years he had employed it in abdominal and vaginal operations of all kinds. The longest operation he had ever performed was one in which he removed a fibroid tumor that weighed eighty-seven pounds, the woman weighing only eighty-five pounds after the tumor was removed. She was in desperate condition and made up her mind after ten years of waiting to have this large mass removed. He operated on her under the use of Schleich solution No. 2, taking two hours and three-quarters to remove the tumor, and only in the latter half hour was it necessary to give her a whiff of ether or chloroform when there was some very painful or sensitive area to work on. The patient recovered. In 1909 he first used local anesthesia for abdominal cesarean section. On January 27 he completed his sixteenth case. These operations had been done under local anesthesia for deformed pelvis, for tumors, and in several cases of placenta previa. The anesthetic employed was Schleich solution No. 2. Within the last two years he had been using novocaine. Some of these sixteen patients were in bad condition, having kidney or lung lesions which rendered them unfit for the safe administration of a general anesthetic. It must be evident to all who did major surgical work of any kind that a procedure which would enable a patient to go through an operation with comparative ease was very valuable and was superior to one that entailed long anesthesia with ether or chloroform. He

could recommend the use of local anesthesia, especially novocaine, for major surgical work only in cases where it would be inadvisable, as in kidney or lung disease, etc., to put the patient under the influence of ether or chloroform.

Scopolamine-Morphine in Abdominal Obstetrics.—Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., said that experience had shown that it was possible to produce satisfactory dämmerschlaf in from 85 to 90 per cent. of the women subjected to this treatment. The satisfactory effect was produced by individualizing the patients, using minimum doses, and under the proper surroundings and environments. The type of woman had much to do with the success or failure of twilight sleep. Intelligent, highly strung, nervous women were the best subjects. It should be distinctly understood that the conduct of labor under scopolamine-morphine anesthesia demanded a fundamental knowledge of obstetrics and the obstetric art. This method of anesthesia insured a better preparation of the soft parts, with diminished trauma, and less liability to intervention and less sepsis. Injuries to the soft parts were minimized, and the greater care and watchfulness given these women during confinement actually made labor safer. The induction of twilight sleep was distinctly a first-stage procedure and should not be begun if the labor was too far advanced. The fetal mortality was lessened by the employment of this form of anesthesia. Its employment had distinct limitation in abnormal cases. Apprehension, restlessness, and physical pain were ameliorated by the use of scopolamine. The contraindications to its use were emergency conditions which arose, such as placenta previa, accidental hemorrhage, eclampsia, prolapse of the cord, primary inertia, and dead fetus. On the other hand it might be used as a first-stage procedure to secure dilation in malposition when such malposition had been recognized. From personal experience in over 175 cases he was led to conclude that scopolamine-morphine anesthesia could be used without detriment to either the mothers or the children in properly selected cases. They were able to diminish the number of operative deliveries and so lessen the amount of obstetric trauma. It was a method for the expert in a maternity hospital, and its greatest usefulness was as a first-stage procedure.

Scopolamine-Narcophine Anesthesia as Used in Freiburg Frauen Clinic.—Dr. KURT E. SCHLOESSINGK of Freiburg, Germany, stated that scopolamine-narcophine anesthesia not only produced amnesia but in most cases analgesia was obtained. Hyoscine, considered by many practitioners to be identical in its action with scopolamine, did not have the same effect as scopolamine. This form of anesthesia was best produced in a half-dark room, as these patients were susceptible to sunlight or noise. The pulse of the mother should be examined, and the fetal heart determined before the first injection was given. This examination should be repeated before each subsequent injection, so that any irregularities in the fetus might be determined. The injections were given intramuscularly. Cases were carefully selected for its use. The number of cases in which forceps was usually required was lessened by this method of anesthesia. There was no shock after delivery. The method was not dangerous to the mother and child.

Scopolamine Amnesia in Labor. — Dr. W. FRANCIS WAKEFIELD of San Francisco had delivered forty women under twilight sleep with the assistance of a carefully chosen and well-trained staff. Each case was carefully selected, and the greatest possible attention was paid to the observance of minute details, without which the highest degree of success was impossible. He had not had a single failure in any of the cases treated. In 80 per cent. of the cases he was able to secure perfect amnesia throughout labor; in 20 per cent. there were occasional breaks in amnesia, so that the patients had slight memory of things, but nothing unpleasant. Efficiently employed this method offered to woman a wonderful panacea. The convalescence of the mother was speedy, and the child had an efficient milk supply.

Dr. JOSEPH B. DE LEE of Chicago was distinctly opposed to the methods by which both the daily press and magazines had made the propaganda for this method of anesthesia. It was bound to produce a renewal of the infantile and maternal mortalities and morbidities the profession went through in 1902 and 1907. Already, by personal communications, he was receiving proof of this fact. The cases for its use must be carefully individualized. He was opposed to broadening the use of this method for general practice. He studied this method of anesthesia in Freiburg while Drs. Kronig and Gauss were in Chicago, and while he might be considered a Jonah the ten cases he saw and studied under Siegel resulted so disastrously that he received a bad impression of spinal anesthesia because he witnessed a death in the clinic at the same time. However, he became convinced there was something in scopolamine analgesia, and since his return from Freiburg he had been using it. The drugs used in producing twilight sleep carried inherent dangers, and the general reemployment of the method advocated ten years ago would result in a repetion of the sad experiences of those days. When the method was practised by specially trained obstetricians in well-equipped hospitals, with trained assistants and nurses, the dangers to mother and child might be reduced.

Dr. HENRY F. LEWIS of Chicago stated that if twilight sleep was a good thing the profession ought to use it. If it was not, it should be discarded on scientific grounds alone, based on experience and a knowledge of obstetrics. If it was going to diminish the use of forceps and curtail the activities of the meddlesome midwife, it was going to do immense good.

Dr. CHARLES S. BACON of Chicago spoke of the medicolegal aspects of twilight sleep, and said to avoid malpractice suits it would be well for practitioners to carry out the reliable technique advised by Kronig and Gauss. While twilight sleep was one thing, the alleviation of pain during labor was not new. Women during labor had been relieved of pain by morphine and atropine, chloral hydrate, alcohol, and other drugs. In difficult and prolonged labors, every one who understood how to handle a case of obstetrics ought to know that a woman could not go through a long stage of thirty or forty hours of dilatation without help. The anesthetic for the second stage of labor was ether, and when twilight sleep was compared with this method of giving relief at the proper time, we should not hestitate to select a simple method in preference to the rather complicated and dangerous method of dämmerschlaf.

Dr. CHARLES E. PADDOCK of Chicago did not think the profession was ready for the general use of the scopolamine-morphine treatment in obstetric cases. No one had presented the indications for its use. When and in what class of cases we were going to give it were questions of great importance. In his obstetric practice he had had only two patients who had asked him to try this method.

Dr. LESTER E. FRANKENTHAL and Dr. JOSEPH L. BAER related their experience with the method in 39 cases at the Michael Reese Hospital, and from the standpoint of interpretation as given by Kronig and Gauss there was no success in 4 primiparæ and 9 multiparæ; very little success in 4 multiparæ, and 1 multipara; partial success in 4 primiparæ, and 3 multiparæ; fair success in 4 primiparæ and no multiparæ; good success in 5 primiparæ and 2 multiparæ; and complete success in 1 primipara and 2 multiparæ.

Local Anesthesia in Thyroid Surgery.—Dr. ARTHUR E. HERTZLER of Kansas City said there were two chief advantages in the use of local anesthesia in goiter work, one of which was the relatively bloodless field that it secured, and the other, that it did away with the cone or mask used for general anesthesia. To secure this bloodless field novocaine and epinephrin were the drugs used. He used this combination for anesthetizing the deeper structures in large goiters or goiters that had undergone inflammation or decalcification, or for unusually difficult cases. He used quinine for the superficial structures. In using this combination he never went beyond 5 grains of novocaine, although many operators used 15 grains or more. Doubtless some of the early manifestations of nervousness produced by novocaine were due to its toxic influences, and until he was quite sure about this he preferred to use as little of the drug as he could. He omitted the preliminary dose of morphine as he thought patients who underwent these operations were better off without a preliminary dose of morphine. This was particularly true of patients with exophthalmic goiter. Nervous patients could be controlled by the use of sedatives.

Local Anesthesia (Nerve Blocking) in General Surgery.—Dr. M. L. HARRIS stated that occasionally there might be slight nausea and vomiting following local anesthesia or nerve blocking, but these were never severe. He had never seen headaches follow nerve blocking which were so common after intraspinal anesthesia. The local solution produced no harmful effects. He had performed 380 operations under nerve blocking, 130 of those being laparotomies. As to the safety

of the method, of the 380 operations, there were nine deaths, but none of them could be attributed to the method of anesthesia. Postoperative pneumonia occurred but once in the 380 cases. After abdominal operations there might be gas pains present, but these were never severe. The range of applicability of the method was constantly increasing with experience. Nerve blocking was not difficult and anyone could use the method successfully who would learn to ligate nerve trunks, study the best way to reach them, and pay proper attention to the technique. The list of 380 operations comprised appendectomies, colostomy, carbuncle of the neck, removal of cervical ribs, cirrhosis of the liver, colectomy, cystotomy, prostatectomy, partial resection of the bladder, cyst of the ovary, epithelioma of the lip, extrauterine pregnancy, fracture cases, gastrostomy, gastroenterostomies, goiters, hysterectomies, etc. The basis of the solution used for anesthesia was novocaine. He had found by experiment that the effect of novocaine was greatly intensified and prolonged by the addition of calcium chloride. The next drug used was magnesium chloride, which accelerated the action of the novocaine.

Dr. Paul F. Morf thought there were some cases well adapted to local anesthesia while others were not. He did not think the most enthusiastic exponent of local anesthesia or nerve blocking would recommend it in all cases of children. Children, no matter whether they were suffering or not during the operation, would naturally be more or less nervous or restless, and for them surgeons would often be compelled to use a certain amount of ether or gas when operating on areas likely to cause much pain. Few patients suffered to any extent from fear of operation. However, this was a variable factor in patients. As to the toxicity of the solutions used, he knew of no case of poisoning on record from the use of proper doses of novocaine. A patient who had great fear of operation would suffer from psychic shock regardless of the fact that no pain might be felt. In patients of this kind an initial dose of morphine, 1/6 grain, and scopolamine, 1/150 grain, from half an hour to an hour before the operation would be a great help.

Dr. J. Rawson Pennington began to block the anorectal region for operations upon the rectum about ten years ago. At that time he found he could inject the anesthetic agent into Alcock's canal and carry some of the solution into the region of the perineum and coccyx posteriorly, but that was not necessary. By injecting the solution into the region of the sphincter muscles and anesthetizing the skin we could dilate the rectum and do many operations upon it. Ninety per cent. of the cases of hemorrhoids could be operated upon in that way. He used cocaine for its immediate effect and quinine and urea for prolonged anesthesia. He had used novocaine but it did not seem to be quite as satisfactory in his hands as cocaine.

Scopolamine-Morphine Anesthesia in Abdominal Surgery.—Dr. Emil Ries stated that scopolamine-morphine anesthesia was valuable as a preliminary adjuvant to other methods of anesthesia. He had used it in combination with spinal, sacral, and local anesthesia, and he had no reason to regret it. The value of the method was not determined by injecting a certain amount of scopolamine and morphine. If one should try to handle the scopolamine-morphine anesthesia in the same way in which he handled a case of ether or choloroform anesthesia he would be disappointed almost every time. Scopolamine-morphine anesthesia would not produce a total loss of consciousness, such as chloroform or ether would produce, unless those drugs were given in such large doses as to make them highly dangerous. With doses of scopolamine and morphine within the limits of safety there was brought about a condition between waking and sleeping, which varied according to the amount of drugs given and the condition of the patient. He could not see why these drugs should be taken out of the hands of the general practitioner any more than ether or chloroform.

Dr. Clifford U. Collins of Peoria, Ill., had used scopolamine-morphine as a preliminary in more than 3,000 cases up to the present time. The preliminary injection of these drugs was not so dangerous as some writers thought. A smaller arount of the general anesthetic was required when scopolamine-morphine was used as a preliminary. There was less postoperative vomiting when scopolamine-morphine was used as a preliminary, followed by ether. The apprehension of impending danger was abolished by this preliminary anesthesia.

Dr. Thomas J. Sullivan could endorse everything that had been said by both Dr. Ries and Dr. Collins as to the use of scopolamine-morphine as a preliminary to ether or chloroform anesthesia. He began the use of scopolamine-morphine as a preliminary in the Post-Graduate Hospital in 1904, and had continued its use ever since with gratifying results.

Philadelphia Neurological Society.

At a stated meeting held January 22, Dr. Frederick H. Leavitt exhibited "A Negro with Saint Vitus' Dance" and he pointed out the apparent rarity of the condition in the colored race.

Dr. Charles W. Burr exhibited "A Case of Hysterical Ataxia" and also "A Case of Senile Paraplegia."

Dr. J. W. McConnell exhibited "A Patient Presenting an Unusual Distribution of Muscular Dystrophy." There was wasting with weakness in the distal portion of the left lower extremity and of the proximal portion of the right upper extremity, together with enlargement and weakness of the right lower extremity and the left upper extremity. The reflexes were diminished and the response to faradic electricity diminished in the affected parts. The condition was looked upon as one of combined myopathy (muscular dystrophy) and myelopathy (chronic anterior poliomyelitis).

Dr. Wm. G. Spiller reported "A Family Form of Nervous Disease Resembling Paralysis Agitans." The disease occurred in three of four brothers and in the one sister. It usually set in in middle life, in the neighborhood of forty years of age. Two of the subjects were alcoholic. The patients exhibited a spastic gait, with exaggerated knee-jerks, at times festination, an immobility of countenance, tremor apart from voluntary muscular action, and a characteristic attitude of the hands. The disorder was considered to be related on the one hand to so-called pseudosclerosis and on the other hand to degenerative disease of the lenticular nucleus.

Drs. Charles K. Mills and Frank presented "A Report on a Case of Ependymoma of the Cervical Spinal Cord, with Wrist-Clonus" and they exhibited the specimen. The patient complained of weakness in the extremities with burning pain in the upper extremities and exaggerated knee-jerks in the lower extremities. A new growth being suspected in the upper cervical region the cord beneath the third, fourth, and fifth cervical spines was exposed, but no tumor or other abnormality was visible. The patient died a short time afterward, and the autopsy, confined to the cord, disclosed noteworthy swelling of the cord corresponding to the cervical enlargement. Section disclosed the presence of a new growth, which histological examination proved to be an ependymoma.

Dr. Charles K. Mills presented a communication entitled "Perseveration and Jacksonian Epilepsy and Motor Aphasia in a Case of Probable Midfrontal Lesion." The patient was a marine in the United States Navy, who, while at the Isthmus of Panama and suffering from pyelonephritis, had an apoplectic seizure, with right-sided paralysis and aphasia. Subsequently, from time to time, he had convulsive seizures, beginning in the right upper extremity and characterized by tonic spasm of the hand persisting in spite of efforts to overcome it. The Wassermann reaction was negative and there were no ocular changes.

Dr. James Hendrie Lloyd exhibited a specimen of "Brain-tumor Involving the Hypophysis Secondarily." The patient had been a man presenting paralysis of the first, sixth, ninth, and twelfth cranial nerves, at first without ocular manifestations, but later developing papilledema, with marked exophthalmos and a copious purulent discharge from the eyes and finally the appearance of papillomata in the nares. An *x*-ray picture had shown destruction of the posterior clinoid processes. A diagnosis had been variously made of poliencephalitis, tuberculoma at the base of the brain and a newgrowth of the pituitary body. Upon post-mortem examination there was found, in addition to the growths in the nares, a neoplasm involving the hypophysis. It was suggested that the tumor had originated from the dura mater and had extended thence to the hypophysis and the nose through the ethmoid sinus.

The following officers were elected for the ensuing year: *President*, Dr. S. D. W. Ludlum; *Vice-Presidents*, Drs. Owen Copp and Samuel Leopold; *Secretary*, Dr. Williams B. Cadwalader; *Treasurer*, Dr. N. S. Yawger; *Councillors*, Drs. Charles K. Mills, M. H. Bochroch, and Charles S. Potts.

Philadelphia County Medical Society.

At a stated meeting held January 27 Dr. William C. Gorgas, Surgeon-General of the United States Army, delivered an address entitled "Sanitation in Panama," illustrated by lantern slides. Dr. Gorgas pointed out that, while the aboriginal Indians of the American tropics and the invading Spaniard were vigorous, both mentally and physically, the striking feature of the latter-day inhabitants of these parts, although a mixture of the two races, is that they are distinctly inferior in both of the respects mentioned. The explanation for this deterioration is to be found not in climatic conditions directly or in changes in the mode of life, but specifically in the influence of the prevalent infectious diseases, and more particularly malarial and yellow fevers. In the four hundred years that the Isthmus of Panama has been known and used as an artery of travel it has been recognized as one of the most dangerous places in the world from the hygienic point of view. By reason of this fact and of the failure of the French in their endeavors to construct a canal between the two oceans at the boundary between North and South America, the results obtained by the American Government in its undertaking are all the more striking and illuminating. After the success that had been attained in Cuba in the eradication of yellow fever, following the demonstration of the part played by the mosquito in the transmission of this disease, similar measures were employed at Panama. Houses were carefully screened, drainage was provided for, shallow collections of water were covered with crude oil, reservoirs for the storage of rain-water to be used for drinking purposes were screened against mosquitos, distilled water was used for this purpose when necessary, and quinine was administered prophylactically. As a result of these measures the morbidity from the two diseases so frightfully prevalent before was greatly reduced and the death-rate from all causes among 6,500 American employees and 3,500 mmbers of their families was kept down to 2.50 per 1,000, a good deal lower than that observed in large cities of the country and as low as the death-rate in the Army, comprising a carefully selected group of men. For a while some of the men lived in barracks, but the outbreak of an epidemic of septic pneumonia led to an investigation, which disclosed that there was too much congestion, and thereafter the men were permitted, when they elected, to build themselves huts and houses and send for their families, with the happiest results. In the pictures were shown, among other things, an ambulance car in which patients were transported to the central hospital, some of the buildings comprising the hospitals at Ancon and at Colon, the screened type of dwelling for employees, shacks erected by negroes, ditch and trench excavations, concreted when intended for permanent use, and the spraying with oil of surfaces of water.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

New York State Board of Medical Examiners.

May, 1914.

(*Concluded from page* 210.)

BACTERIOLOGY.

Candidates must answer questions 1, 2, and 3.

1. How would you determine the presence or absence of tubercle bacilli in sputum?

2. How would you estimate the number of bacteria in a sample of cow's milk? What value have such estimations in determining the safety of the given milk for feeding a child?

3. What is (*a*) active immunity, (*b*) passive immunity? Give an example of each.

Candidates must answer two of the following questions, but no more.

4. What is tuberculin (old tuberculin) and how is it obtained?

5. Given a specimen of fluid withdrawn by lumbar puncture from a case of meningitis, how would you determine by bacteriological methods whether the meningitis is due to tubercle bacillus, to meningococcus, or to other pyogenic cocci?

6. What kind of wound is likely to be infected with tetanus bacilli and to favor their growth?

DIAGNOSIS.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. Describe the microscopic differences between sarcoma and carcinoma.

2. What are the signs of glaucoma?

3. Name and describe some of the more common syndromes found in syphilis of the nervous system.

4. What symptoms indicate a fracture of the base of the skull?

5. What are the physical signs of lobar pneumonia?

6. Give the points in the differential diagnosis between primary cancer of the stomach and ulcer of the stomach.

7. Describe the symptoms of acute postoperative gastroenteric paresis (acute dilatation of the stomach) and tell how they differ from those of ordinary post-anesthetic vomiting.

8. What are the signs of intussusception in the child?

9. What are the symptoms of calculus descending the ureter?

10. What are the most common symptoms of obstructive hypertrophy of the prostate?

11. What disability is produced by anterior dislocation of the head of the humerus?

12. Describe the early symptoms of Pott's disease (tuberculosis) of the spine.

ANSWERS.

BACTERIOLOGY.

1. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

2. *Method of estimating the number of bacteria in milk:* "In estimating the number of bacteria in milk, colony counting in a jar or gelatin plates is resorted to. Great care must be exercised in obtaining the specimens. If taken from a can the contents of the can should be thoroughly mixed, since the cream usually contains many more bacteria than the rest of the milk. The specimen is then taken into a sterile test-tube or flask. If the milk is supplied in an ordinary milk bottle, this should be thoroughly shaken before being opened, and the specimen for examination taken out with a sterile pipette. Dilutions of the specimen can be made in sterile broth or salt solution. If an initial dilution of 1:100 is made, quantities ranging from 1 c.c. to 0.1 c.c. of this will furnish 0.01 to 0.001 c.c. of the milk, respectively. Inoculation of properly cooled tubes of melted neutral agar and gelatin, with varying quantities of these dilutions are then made and plates poured. After twenty-four to forty-eight hours at room temperature or in the incubator, colony counting is done in the usual manner with a Wölffhügel counting plate. In samples in which few bacteria are expected, direct transference of 1/20 or 1/40 of a c.c. of the whole milk into the agar may be made. This saves time, but is less accurate than the method given above." (Hiss and Zinsser's *Bacteriology.*) The safety of the milk depends on the kind of bacteria as well as the number; but Park and Holt conclude that milk containing over one million bacteria to the cubic centimeter is certainly harmful to the average infant.

3. "*Immunity* is called *active* when the animal protects itself through its own activities, *passive* when its protection depends upon defensive substances prepared by some other animal and forced upon it. Thus, if a frog be injected with anthrax bacilli, the leucocytes devour the bacteria, destroy them, and so protect the frog from infection, the immunity is *active* because it depends upon the activity of the frog's phagocytes. But

if a guinea-pig previously given antitetanic serum be injected with tetanus toxin, and so recovers from the toxin, the resisting power, conferred by the antitoxin previously injected, does not depend upon any activity of the animal infected, which remains entirely passive."—(McFarland's *Text-book on Pathogenic Bacteria.*)

4. *Tuberculin (old tuberculin)* is a preparation made from cultures of tubercle bacilli. These cultures, grown in 5 per cent. glycerin bouillon, are filtered, and the filtrate is then evaporated to 1/10 of its original volume.

5. "Examination of the fluid obtained by lumbar puncture is of value in diagnosis of certain forms of meningitis. *Tubercle bacilli* can be found in the majority of cases of tuberculous meningitis. The sediment, obtained by thorough centrifugalization or by coagulation and treatment with antiformin, is spread upon slides and stained by one of the well known methods. A considerable number of smears should be examined. In doubtful cases inoculation of guinea-pigs must be resorted to. The *diplococcus intracellularis meningitidis* is recognized as the cause of epidemic cerebrospinal fever, and can be detected in the cerebrospinal fluid of most cases, especially those which run an acute course. Cover-glass smears from the sediment should be stained by the method used for the gonococcus. The meningococcus is an intracellular diplococcus which often cannot be distinguished from the gonococcus in stained smears. It, also, is decolorized by Gram's method. The presence of such a diplococcus in meningeal exudates is, however, sufficient for its identification. Various organisms have been found in other forms of meningitis—the *pneumonococcus* most frequently. In some cases no micro-organisms can be detected even by culture methods." (Todd's *Clinical Diagnosis.*)

6. The kind of wound likely to be infected with the tetanus bacilli is a punctured wound, or one made by an instrument contaminated with soil.

DIAGNOSIS.

1.—

SARCOMA.	CARCINOMA.
Origin; entirely mesoblastic (Connective-tissue type).	Epiblastic and hypoblastic (Epithelial-tissue type).
Stroma; intercellular. Rarely forms alveoli.	Vascular connective tissue, which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
Cells; granulation tissue or embryonic connective-tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
Intercellular substance; may be present.	Absent, or merely fluid.
Vessels; embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective tissue stroma, and supported by the walls of the alveoli. Seldom in contact with the cells.

—(Coplin's *Pathology.*)

2. *Signs of glaucoma*: Increased ocular tension, hazy cornea, pupil sluggish and widely dilated, cupping of optic disc, and visible pulsation in the retinal arteries.

3. "Syphilis of the brain in its most common form shows itself by a gradual development of severe and persistent headache. This is usually associated with vertigo, sometimes with nausea and vomiting. After the headache has developed and has lasted for a time, or even without much delay, there comes on sometimes an attack of hemiplegia, there are paralyses of the cranial nerves, more especially of the nerves of the eye. Optic neuritis is somewhat frequent. There may be, before any paralyses develop, attacks of epileptic convulsions, either general or partial. Without any paralyses or with simply cranial-nerve paralyses, there may develop attacks of somnolence and coma. Even if such attacks do not appear, the patient often shows a mental irritability and weakness, a slowness of the reasoning process, and incapacity to fix the attention such as is observed in connection with brain tumors, only with nerve syphilis these symptoms are not usually so marked. Polyuria and polydipsia are symptoms which are occasionally met with." (Dana's *Nervous Diseases.*)

4. *Symptoms of fracture of base of skull*: Hemorrhage (from nose, into orbit, from ear, or into tissues), escape of cerebrospinal fluid from nose or ear; concussion or laceration of brain, with coma; various nerve lesions (blindness, ocular paralysis, facial paralysis, deafness).

5. *Physical signs of lobar pneumonia*: "*Inspection* reveals during the first stage deficient movement of the affected side, due to pain. The apex-beat is normal in situation, and the interspaces do not bulge. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air, the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation* during the first stage shows the vocal fremitus to be more distinct than normal, especially over the diseased portions. In the second stage, the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion*—In the first stage, the percussion note is slightly impaired at times, having a hollow or tympanitic quality. In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining areas the resonance is increased (Skoda's resonance). *Auscultation.*—In the first stage there is heard over the affected part a feeble vesicular murmur, associated with the true vesicular or crepitant (crackling) râle, heard at the end of inspiration only. In the second stage there is harsh, high-pitched, bronchial respiration, at times resembling a to-and-fro metallic sound, except in those rare instances in which the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage, the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitatio redux) returns. As resolution proceeds, the breath sounds are associated with large and small moist and bubbling râles."—(Hughes' *Practice of Medicine.*)

6.—

CANCER.	ULCER OF STOMACH.
Is rare under forty years of age.	Usually in young adults, especially women.
Epigastric pain is more or less continuous, and not much relieved by vomiting.	The pain is rendered worse by food, and vomiting gives much relief. The pain is also more localized and xiphi-vertebral in character.
Anorexia is marked.	Appetite is good, but the patient is afraid to eat.
Vomiting is not frequent, but is copious; and in the vomited matter the Oppler-Boas bacillus may be found. Cancerous fragments are rare. Free HCl is diminished or absent, and lactic acid is often present.	Vomiting is frequent, and the vomited matter contains free HCl often in excess.
Hemorrhage is seldom copious, but may be frequent ("coffee-ground" vomiting); most common in the later stages.	Hemorrhage is not so frequent, but is copious at times. May be the first symptom.
Loss of flesh; the development of cachexia is rapid.	When the gastric symptoms are severe and prolonged, a cachectic appearance may develop, but never to the same extent as in cancer.
Epigastric tumor is usually easily detected.	No epigastric tumor, though there may be some rigidity of the rectus.

—(Wheeler and Jack's *Handbook of Medicine.*)

7. *Acute postoperative gastroenteric paresis (acute dilatation of the stomach)*: "The earliest and most common symptom is nausea and vomiting. This may begin soon after recovery from the anesthesia, increasing

in severity in proportion to the degree of dilatation. In other cases it may not begin until the second or third day following the operation. The vomiting can be distinguished from the ordinary postoperative vomiting by the gradual increase in the quantity of fluid. Enormous quantities of thin brownish sour fluid are vomited. The emesis is accompanied by symptoms of collapse. The upper half of the abdomen is at the same time much distended and tympanitic on percussion. The temperature is either normal or subnormal, the pulse increased in frequency, and the urine either greatly diminished or there is complete suppression. The heart is displaced upward by the greatly dilated stomach. Percussion over the precordium and left side of the chest shows a marked tympanitic note. The displacement of the heart and left lung is the cause of the rapid, weak pulse, the cyanosis, and dyspnea so characteristic of these cases. Through the stomach-tube an enormous quantity of brownish fluid escapes, great improvement occurring after gastric lavage. The change in contour of the upper half of the abdomen, and the decreased area of tympany after every expulsion of vomitus, show that this fluid is not free in the peritoneal cavity. Many of the milder cases recover spontaneously, although the majority end fatally unless speedy relief, by gastric lavage, etc., is given. . . . If the vomiting is due to the anesthetic, it should begin to diminish in frequency during the second twelve hours after the operation. In addition, the vomitus consists simply of mucus with a small amount of bile. There is no abdominal distention, and when the high rectal tube is inserted or an enema is given, the patient is able to expel flatus."—(Eisendrath's *Surgical Diagnosis.*)

8. INTUSSUSCEPTION IN CHILDREN. *Symptoms:* "These come on very suddenly in the midst of health, with a sharp cry or scream. The child turns pale and vomits; it kicks and tumbles about as if suffering from colic. The bowels are relieved at once of whatever is below the seat of obstruction, and some are deceived by this circumstance; this is followed by straining, which brings away nothing but mucus and blood. Palpation will generally detect a round lump or sausage-shaped and painful swelling in the region of the ascending colon or in the left iliac fossa. A marked depression in the right iliac fossa may be present, owing to the absence of the cecum, which is dragged over to the left. A careful rectal examination should now be made, and the presence of a rounded tumor, which closely resembles the os uteri in outline, would confirm the diagnosis. In severe and urgent cases the tumor may protrude at the anus, but this is a rare event. The temperature is normal or subnormal in the absence of peritonitis. Vomiting and straining continue, and soon the pinched look and sunken eyes proclaim the seriousness of the case. Unless prompt relief is at hand death quickly ends the child's sufferings."—(McCaw's *Discases of Children.*)

9. The *symptoms of calculus descending the ureter* are severe colic in the ureter, tenderness over the same region, hematuria; the urine may also contain pus; *x*-ray may show presence and location of the calculus; there may be an abdominal tumor over affected area.

10. *Symptoms of obstructive hypertrophy of the prostate:* Increased frequency of desire to urinate, particularly at night or in early morning, with difficulty in starting the stream; there is much residual urine, as may be demonstrated by catheterizing the patient just after urination; urine may dribble away; if the obstruction is complete, the patient cannot urinate; rectal examination will disclose the hypertrophy, but not the extent of the obstruction; the prostatic urethra is larger than usual, and catheterization may be difficult.

11. In anterior dislocation of the head of the humerus, the patient cannot place the hand of the injured side on the opposite shoulder, and voluntary movements of the dislocated joint are impossible.

12. *Pott's disease of spine:* "There are three typical signs: pain, rigidity, and deformity; and there may be abscess and paraplegia. Rigidity is the most important of these signs. 1. *Pain.*—In the early stages it may be only of an aching character. Local pain is that felt in the situation of the diseased bones, and tenderness may be elicited by percussion over the spinous processes. Referred pain is produced by pressure on the roots of nerves in the intervetebral foramina, and is felt at their cutaneous terminations. If in the lumbar region pain may be felt in the legs; if in the dorsal region, pain may be felt in the abdomen, chest, or arms; if in the upper cervical region, pain may be felt over the upper part of the chest or back of the head. 2. *Rigidity* is invariably present. In the early stages it is due to muscular contractions to steady the painful part. In an adult it can be demonstrated by getting him to go through various movements while a hand is kept over the suspected area. The limitation of movement is better felt than seen. In a child, it is better to lay it on its face and test the flexibility by grasping the ankles, and so raising the legs and pelvis. If rigidity is present, the whole body is raised instead of the back being curved. In the later stages, when repair has taken place, the rigidity is due to bony ankylosis. Secondary curvatures restore the upright position of the body. 3. *Deformity* is due to falling forward of the upper part of the spine as the vertebral bodies become destroyed, so that cases cured in the early stages present none. Where only two are involved the deformity is angular; where a large number are affected the deformity is a curvature. When the curvature is in the dorsal region, the sternum becomes convex anteriorly, and the intercostal spaces are diminished or obliterated."—(*Aids to Surgery.*)

Gonococcus Septicemia Following Scarlet Fever.—M. Nicoll, Jr., reports three cases of arthritis occurring in children during convalescence from scarlet fever in the Willard Parker Hospital. The presence of an eruption not usually seen in cases of scarlatinal arthritis suggested the taking of blood cultures, the existence of a gonococcus septicemia. In two of these cases gonococcus vaccines were used, and in one in addition gonococcus serum was employed. In the third case the treatment was purely symptomatic. All of the patients recovered. The point is emphasized that gonococcus infection of the blood in childhood is less serious than in adult life and the tendency to destructive heart lesions in the former is less pronounced.—*Archives of Pediatrics.*

Miscellany.

One Memorable Field Day.—The medical man of an unattached reserve company which was present at the battle of Lorraine describes in detail (*Berliner klinische Wochenschrift*, November 2) the experiences of August 25th, after a 5-hour march in weather of the hottest kind. The company had bivouacked for three hours and were again on the move at daybreak. After coffee had been served they soon reached the battlefield. Here they lay for hours under cover, for they were among the reserve troops, until they received the order to advance. It was now high noon, and they halted at a high brush fence. Here many wounded without any medical aid were seen tottering to the rear. Thirst was universally present, with no water in prospect. Then the severely wounded began to appear, supported or even carried by their comrades.

There was a reservist shot through the chest, with the air whistling through the wound at each breath. The author, who was giving first aid to all, his status being that of a free lance, as he was answerable to no superior medical officer, bound up the man's chest, gave him morphine, and passed him along. Some wounds of the abdomen were fortunately tangential, sparing the peritoneum. But there were arms defleshed, legs shot through—many wounds contained shrapnel bullets, some of which could be felt under the skin. All these wounds were promptly dressed and with no pretence at asepsis—there was not even water available. Thirty wounded were thus attended to and directed to a Red Cross wagon which had been visible in the distance, but had later been forced by the shell fire to move back. At this juncture the word came to the reserve company to advance and the doctor was therefore obliged to discontinue his self-imposed labors.

Odd Aspects of Tetanus.—As a rule the numerous cases of tetanus among warring troops in Europe have fallen readily into certain types. Little has been said of anomalous types such as cryptogenic and rheumatic tetanus; nor has horse tetanus been mentioned, so far as we know. In one of the Military Medical Evenings held at Namur in November (*Deutsche medizinische Wochenschrift*, December 17), Heuss spoke of an equine epidemic, in a certain riding school for officers, which was stamped out by prophylactic injections of antitoxin. Several similar episodes are recorded; also an epidemic in a cavalry regiment in which the disease continued to spread in the absence of efforts at immunization.

Of especial interest were two cases of tetanus without visible wounds. In one patient out of 27, no wound could be found. The man had bad teeth and many carious roots. Of the entire series but four recovered. Whether the cryptogenic case was included in this series is not stated. In another case in the practice of another surgeon no wound was found although the disease was of severe type. For ten days the diagnosis was chronic rheumatism. The patient slowly recovered under intensive treatment. A slight wound in the margin of the gum was found, and thought to be the port of entry. It is possible that in these cryptogenous cases harmless tetanus bacilli in the circulating blood may have been activated by small suppurative lesions of the gums. Such possibilities have recently been demonstrated experimentally.

A METHOD OF FEEDING INFANTS WITH PRECISION.

BY ALBERT E. MUCKLOW, M.D.,

BROOKLYN, N. Y.

IMPRESSED with the fallacies of the many and varied infant feeding doctrines and prompted by the ease with which fermented milk was assimilated in typhoid and other febrile states, I began in 1907 to employ such milk in the feeding of infants. While the results from the first have been remarkable, it has only been possible to establish a precise method by acquiring a knowledge of the following: (1) The percentages of fat, proteins, and sugar found in rich human milk. (2) The variation in the composition of cow's milk. (3) The reaction of human milk to rennet. (4) The reaction of cow's milk, fermented and unfermented, to rennet. (5) The kind of culture best suited for fermenting the milk. (6) The means of insuring a viable culture. (7) The temperature and time required for the fermentation. (8) The means of obtaining and maintaining cow's milk with a low bacterial count. (9) The composition of the various layers in cow's milk of different degrees of richness. (10) The means of determining in practice the richness of cow's milk.

The stereotyped statement that human milk contains 4 per cent. fat may be correct for average human milk but does not apply to the best. The latter should be our standard. The teaching that cow's milk contains fat 4 per cent., proteins 4 per cent., and sugar 4 per cent. may be easily memorized, but is erroneous.

Milk personally withdrawn from five young, healthy mothers nursing infants of unusual robustness, two to five months of age, care being taken to empty the full breasts thereby obtaining both the fore milk and strippings, showed, upon analysis by Dr. Moak, that rich breast milk, exclusive of colostrum, contains,—

HUMAN MILK

Fat	5.50 per cent.
Proteins	1.50 per cent.
Sugar (lactose)	6.50 per cent.

The findings in a series of analyses of certified cow's milk were as follows:

COW'S MILK

Fat	4.00 to 5.60 per cent.
Proteins	2.98 to 3.65 per cent.
Sugar (lactose)	4.62 to 4.90 per cent.

Cow's milk after standing contains in its upper layers a larger percentage of fat and smaller percentages of proteins and sugar than in the lower strata. The composition of human milk can be approximated by diluting these top layers with water and making up, with whole milk and sugar, any deficiency of proteins and sugar caused by the dilution.

Upon contact with rennet the casein of human milk precipitates as a soft, flocculent curd, while that of cow's milk coagulates into a firm clot which shrinks into a leathery, stringy mass. This difference has been the *bête noire* of artificial infant feeding. Adding cereal decoctions to cow's milk to mechanically separate the coagula, thereby making many small tough curds in the infant's stomach instead of a few large ones, does not solve the problem. Diminishing the amount of proteins in the mixture below that which is required and making up the calories with an excess of carbohydrates, is likewise not meeting, but running away from the issue.

If a culture of Bulgarian bacilli is added to cow's milk the bacilli will proliferate. During their propagation they will convert part of the lactose into lactic acid. This nascent lactic acid will combine with the casein and precipitate it in the form of a soft, flocculent curd upon which rennet has no effect.

Tests made in the laboratory of Fairchild Brothers and Foster demonstrated that when milk containing the culture is kept in a temperature of 98° to 100° F. for forty-eight hours, the splitting up of the lactose into lactic acid continues until at the end of this period 2.60 per cent. of lactic acid is produced. This amount arrests the growth of the Bulgarian bacilli. If, on the other hand, the milk with its contained culture is kept in a temperature of 80° to 100° F. for twenty-four hours, the casein is precipitated into the same flocculent curd as in the former instance, but there is formed only 0.69 per cent. of lactic acid. It was also observed that this small amount could be decreased to 0.55 per cent. by adding one grain of bicarbonate of soda to each ounce of the fermented milk. The undesirable effect of neutralizing all the acidity and thereby redissolving the coagulated casein does not result from the addition of this amount of bicarbonate of soda. It does, however, reduce the acidity sufficiently to make the milk very palatable. The 0.69 per cent. of lactic acid is formed, as stated above, by the splitting up of some of the lactose. Therefore the sugar content of the milk will be lessened by just that amount.

The Bulgarian Bacilli Culture.—This is the *sine qua non* of the entire method and deserves more than passing mention. Cultures of this bacillus are obtainable in liquid and tablet form. The liquid cultures when added to milk and placed in the proper temperature immediately begin to proliferate and ferment the milk. The results from their use are uniform. The tablets contain a desiccated culture, the bacilli being in a state of suspended animation. When these are added to milk a varying period of time elapses before they respond and

exhibit evidences of growth and action. The results from their use are uncertain and disappointing. Unless the vials containing the liquid cultures are kept in a low temperature, the contained bacilli will proliferate and, consuming the limited amount of pabulum present, soon perish. A dozen vials should be purchased as often as required direct from the laboratory of the manufacturer, immediately placed on ice, and there kept until used. This will insure a viable culture. The contents of a vial holding between 6 and 7 c.c., each c.c. containing an average of three hundred and eighty million Bulgarian bacilli, is the correct amount to add to each pint of milk or fraction thereof to be fermented. The culture in the vials is employed only every fourth day. On the other days to each pint of milk or fraction thereof to be fermented is added one-half teaspoonful of a previously fermented milk. Each vial should be agitated just before pouring out its contents lest some of the bacilli which form a copious sediment may remain in the vial.

The milk while fermenting should be undisturbed and kept constantly in a temperature of 80° to 100° (best 90°) F. for twenty-four hours. To maintain a uniform temperature I have devised a semi-circular, sheet-iron compartment to hold the jars containing the milk. Its widest transverse measurement is 18 inches; its outside height 15 inches, and its inside height 10 inches. It is enclosed, excepting a semi-circular opening in front. This opening tapers from a 7-inch width below to a 4½-inch width above. The floor upon which the jars of milk rest is 5 inches above the base and its edge is protected at the front opening by a ⅜-inch lip. Inside the compartment hangs a thermometer. In front stands either a Simplex Plain Portable Electric Stove No. 1731, or a Dietz's No. 2 Climax Square Station Lamp fount fitted with a size B burner (not the burner depicted in the illustration, as this was discarded on account of it giving off too much heat) and a Macbeth pearl top chimney No. 504. An equipment, exclusive of the electric stove, is made by Mr. Charles Emmet, of 763½ Gates Avenue, Brooklyn, N. Y., consisting of the semi-circular metal compartment, lamp, thermometer, Chapin cream dipper, fine meshed strainer, four one-quart preserve jars, a two and a half quart agate pitcher, and two one-pint glass tumblers. A vertical section of the fermenter and a full armamentarium, excepting the agate pitcher and pint tumblers, which have been added since the photograph was taken, are shown herewith.

The milk should have a low bacterial count at the time of milking. This should be maintained by bottling immediately after milking and then keeping it in a temperature of 40° to 50° F. The latter can be accomplished by the bottles being covered with cracked ice from the time of bottling until delivered; by the consumer immediately placing them in the ice chamber of a refrigerator either next to the ice or, better, in a pail full of cracked ice, and there keeping them until the required amount has been dipped off. The amount removed should be implanted immediately with a culture of Bulgarian bacilli, poured into a preserve jar and sealed. The Bulgarian bacilli, if placed in a temperature of 80° to 100° F., will rapidly multiply and inhibit the few other bacteria present in this originally low bacterial count milk. After the milk has fermented for the desired length of time and the other ingredients have been added, the completed mixture should be placed, in sealed jars, either next to the ice or in cracked ice and there kept until used. The diluent should be cold water that has either been distilled, or boiled for 5 minutes. All utensils should be sterilized.

Fig. 1.—Apparatus for fermenting the milk.

Certified Milk should be employed. This has a low bacterial count; is milked and immediately bot-

tled under the best sanitary conditions; the milkers and dairy employees are typhoid immunes, and the cows are tuberculin tested. However, it varies considerably in composition due to differences in the character of the herds of the several certified farms.

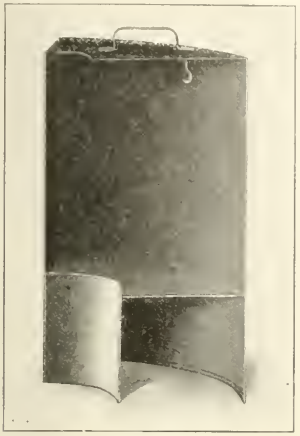

Fig. 2.—Vertical section of fermenter.

Records of the weekly examinations for fat content by the Milk Commission of the Medical Society of the County of Kings show that this ranges from 4.00 to 5.60 per cent. To determine the composition of the various layers in milks of the above different degrees of richness, a series of analyses were made for me by Dr. Harris Moak, bacteriologist and chemist of the aforesaid Commission. The consummation of the above undertaking was made possible through the courtesy of Borden's Condensed Milk Company, who, from purely scientific motives, placed at our disposal one hundred and ten cows on their farm at Wallkill, N. Y., and their well-equipped laboratory in New York City.

Dr. Moak, after spending considerable time and effort and after many fruitless attempts, finally succeeded in assembling five herds of cows in such a manner that the mixed milk from each herd contained, respectively, 4.00 per cent., 4.40 per cent., 4.80 per cent., 5.20 per cent., and 5.60 per cent. of fat. These he termed groups A, B, C, D, and E.

That the findings might be of practical value, the milk was mixed and bottled immediately after milking and shipped to the city in the regular manner of handling Certified Milk. The amount required from each bottle for analysis was dipped off thirty-six hours after milking, which approximates the interval that elapses between the milking and delivering of Certified Milk to the consumer. The milk was removed from the bottles in the ordinary domestic manner; namely, by means of a Chapin cream dipper (holds one fluid ounce) excepting the first dipperful from each, this being taken off with a teaspoon. The depth of the cream layer in each bottle was noted so that the richness of a given bottle full of milk might be known by the number of dipperfuls of cream it contained.

The findings in the first table on page 298 represent in each instance the average of two to six analyses.

The maximum bacterial count of the milk before, during, and at the end of the analyses was two thousand per c.c. Hence, bacterial action had practically no effect upon the findings.

The methods employed in determining the fat, proteins, and sugar, respectively, were Leffman and Beam's modified Babcock, the standard Kjeldahl, and the Fehling's gravimetric. The total solids were determined by drying and weighing.

It was observed while making the examinations that the contents of a bottle full of milk could invariably be made of uniform composition by pouring it into a pitcher, then back into the bottle, and repeating this procedure once; namely, four pourings in all.

The bottles full of	4.00%	Fat Milk contained a trifle less	than	5	dipperfuls of cream.
" " " "	4.40%	" " "	"	5½	" " "
" " " "	4.80%	" " "	a trifle more than	6	" " "
" " " "	5.20%	" " "	"	6½	" " "
" " " "	5.60%	" " "	a trifle more than	7	" " "

Smaller measurements than half dipperfuls are impractical in estimating the depth of the cream layers. Hence, the deductions which may be made for every day use are:

4.00% Fat Milk	4.40 to 4.80% Fat Milk	5.20 to 5.60% Fat Milk
Cream layer, less than 5½ dipperfuls	Cream layer, 5½ to 6 dipperfuls	Cream layer, more than 6 dipperfuls

The depths of cream given above and the composition of the various layers in the first table on page 298

apply only to milk that has been bottled immediately after milking and undisturbed after bottling. Dr. Moak allowed milk to stand for two hours after milking and then mixed and bottled it. The cream layer of this milk, even thirty-six hours after bottling, was deeper but rarer, containing smaller percentages of fat, proteins, and sugar than the cream layer of the same kind of milk bottled immediately after milking. Thus even a partly risen cream, if disturbed, will not subseqently rise to the same density as it would have done if undisturbed. Hence, the richness of a bottle full of milk that has been disturbed cannot be judged by the depth of its cream layer.

As seen above, rich breast milk has been taken as our standard. Infants during the first few weeks do not need the proteins found in such rich milk; the age at which they do, varies. A series of formulas are therefore necessary to enable us to increase the proteins, according to requirements, from a small percentage during the first few weeks to the amount found in the richest breast milk and finally to the quantity occurring in undiluted cow's milk.

The majority of healthy infants will require the several formulas at the ages given below. However, we must individualize. A child progressing favorably with a given formula may continue upon it a few weeks longer than indicated in the schedule. Conversely, a failure to steadily gain in weight should prompt us to advance to a stronger formula earlier than directed. During the first six months a weekly gain of eight ounces together with normal stools is desired. An infant marantic from previous faulty feeding should, on account of the low ebb of its assimilative functions, be given for a time a mixture weaker than that indicated by its age, the subsequent use of richer ones being permitted with the return of full absorptive powers as shown by the continuance of normal stools under such advance.

Malt sugar is better tolerated than commercial lactose or cane sugar; hence, in raising the sugar content of the mixture to 6.50 per cent. we may with impunity add a non-alcoholic malt extract, such as Kepler or Loeflund's. The specific gravity of these is about 40 per cent. higher than that of milk. They contain, however, only 70 to 75 per cent. of combined maltose and dextrin; therefore one ounce

Age in Months	4.00% Fat Milk — Cream Layer, Less than 5½ Dipperfuls							4.40 to 4.80% Fat Milk — Cream Layer, 5½ to 6 Dipperfuls							5.20 to 5.60% Fat Milk — Cream Layer, More than 6 Dipperfuls

Composition of Formulas
Fat varies from 5.50 to 5.68% in each.
Proteins gradually increase from 0.55% in 1st to 2.05% in last.
Sugar 6.50% in each.

Composition of Formulas
Fat varies from 5.51 to 5.70% in each.
Proteins gradually increase from 0.63% in 1st to 2.13% in last.
Sugar 6.59% in each.

Composition of Formulas
Fat varies from 5.53 to 5.64% in each.
Proteins gradually increase from 0.73% in 1st to 2.03% in last.
Sugar 6.59% in each.

by volume represents approximately one ounce by weight of combined maltose and dextrin.

The amount of malt is estimated in dipperfuls and half dipperfuls on account of its high specific gravity making smaller measurements impractical.

In practice it will be necessary to increase by one-half or to double the amounts of most of the above formulas, the smaller quantities having been given in the tables to make the calculations easier and the descriptions more lucid.

The richness of the bottle full of milk used in preparing the first formula may be determined as follows:

Dip off the top 4 dipperfuls into a pint tumbler and the 5th dipperful into a second pint tumbler. If less than ½ dipperful of cream remains, consider the original contents of the bottle as a 4.00 per cent. fat milk. Use the 4 dipperfuls in the first tumbler as the top milk in the formula: or,

Dip off the top 4 dipperfuls into a pint tumbler and the 5th dipperful into a second pint tumbler. If only ½ to 1 dipperful of cream remains, consider the original contents of the bottle as a 4.40 to 4.80 per cent. fat milk. Mix the 4 dipperfuls in the first tumbler and the 1 dipperful in the second tumbler and use these 5 dipperfuls as the top milk in the formula: or,

Dip off the top 4 dipperfuls into a pint tumbler, the 5th dipperful into a second pint tumbler, and retain the 6th dipperful in the dipper. If some cream still remains, consider the original contents of the bottle as a 5.20 to 5.60 per cent. fat milk. Mix the 4 dipperfuls in the first tumbler, the 1 dipperful in the second tumbler, and the 1 retained in the dipper and use these 6 dipperfuls as the top milk in the formula.

In preparing the subsequent formulas, it will be more convenient to adopt the following procedure:

Dip off the cream from the bottle from which the whole milk is to be taken. Note the number of these dipperfuls in order to determine the richness of the milk. Mix the cream thus dipped off with the rest of the contents of the bottle from which it was removed.

The calculations by which the formulas are obtained are shown below.

Age: 2 to 4 Months	4.40 to 4.80% Fat Milk							
	% Fat	% Prot.	% Sug.	Parts	% Fat	% Prot.	% Sug.
Top 5 oz. containing after fermentiag.	23 90	2.71	3.39	= 1	23 90	2.71	3.39
Whole Milk 5 " " " "	4 60	3.20	4.11	= 1	4 60	3.20	4.11
Water 15 " "				= 3			
				5)	28 50	5.91	7.50
The above 25 oz. will thus contain					5 70	1.18	1.50
6.50% − 1.50% = 5.00% = percentage of additional sugar needed.							
25 oz. × 5.00% = approximately 1 oz. = amt. of sugar required by weight.							
1 oz. by volume of the malt ext. = approximately 1 oz. by weight of combined maltose and dextrin. Therefore, replacing 1 oz. of the water with 1 dipperful (1 oz. by volume) of the malt ext. adds approximately 5.00% of combined maltose and dextrio.							5.00
Composition of complete mixture					5.70	1.18	6.50

The practical application of the above principles can be best shown by the following instructions for the guidance of the mother or nurse.

Age: 2 to 4 Months	4.40 to 4.80% Fat Milk

Dip off into a pitcher the cream from a quart bottle full of milk that has not been disturbed. Note the number of these dipperfuls in order to determine the richness of the milk. Pour the rest of the contents of the bottle into the same pitcher. Pour the entire amount back into the bottle. Again pour the contents of the bottle into the pitcher and back into the bottle; that is, four pourings in all.

Dip off into the empty pitcher 5 dipperfuls of this mixed milk.

Skim off the top 5 dipperfuls from another quart bottle full of milk that has not been disturbed and add these to the above milk in the pitcher.

Add either the contents of a vial of the Bulgarian bacillus culture (add this every fourth day) or ½ teaspoonful of the preceding day's fermented milk.

Pour into a quart preserve jar. Seal it and stand without disturbing in 80° to 100° (best 90°) F. for 24 hours.

Rub through a fine meshed strainer to make the flocculi small enough to pass readily through the hole in the nipple. Be sure to leave none on the strainer.

Excepting every fourth day take ½ teaspoonful of this and add it to the next milk to be fermented.

Add to the above fermented and strained milk a 10 grain powder of bicarbonate of soda, accurately weighed.

Add 14 dipperfuls of cold water that has either been distilled, or boiled for 5 minutes.

Add 1 dipperful of malt extract.

Pour the completed mixture into two quart preserve jars. Seal them, immediately place in the ice chamber of a refrigerator either next to the ice or, better, in a pail full of cracked ice, and there keep them until needed. At feeding time shake well, pour out the required amount, then immediately reseal the jar, and replace it on ice. The amount poured out should, without delay, be warmed and fed.

The method by which the amount of the above mixture may be doubled is obvious. It may be increased by one-half as follows:

Dip off into a pitcher 7½ dipperfuls from a bottle full of mixed milk.

Skim off into a pint tumbler the top 5 dipperfuls from each of a second and a third quart bottle full of milk that has not been disturbed. Pour these 10 dipperfuls into another pint tumbler, then back into the first tumbler, and repeat this procedure once; that is, four pourings in all. Add only 7½ dipperfuls of these to the above milk in the pitcher. Add 1½ times the above amounts of the other ingredients.

Note: All utensils should be placed in a large kettle full of water and boiled for 5 minutes just before using them.

The first dipperful from a bottle full of milk should be removed with a teaspoon to avoid spilling.

The infant should be satiated, the average requiring:

1st	week	1	-1½ oz. every	2	hours by day and twice at night.
2nd	"	1½-2	" "	2	" " " " " " "
3rd	"	2	-2½ " "	2	" " " " " " "
4th	"	2½-3	" "	2	" " " " " " "
1- 2	mos.	3	-3½ " "	2	" " " " " " "
2- 4	"	3½-5	" "	2½	" " " " once " "
4- 6	"	5	-6	2½-3	" " " " " " "
6- 8	"	6	-7	3	" " " only.
8-10	"	7	-8	3	" " " "
10-12	"	8	-9	3½	" " " "
12-14	"	9	-10	3½	" " " "

Feedings should be warmed by standing nursing bottle containing same in water not hotter than hand can bear, as too great a heat will toughen the curd.

Use a medium sized nipple with a single opening. Make opening the proper size by running through it the red hot point of a No. 7 sewing needle, the eye end of the needle being inserted into a cork to protect the fingers. After each nursing turn the nipple inside out, scrub clean and place in borax water (one heaping teaspoonful of borax to a cupful of cold, boiled water).

Use of the above method for the last seven years in over two hundred cases in private practice, has demonstrated the fact that by strictly observing the aforecited details, infants can be artificially fed with precision as shown by normal stools, perfect dentition, and a development and robustness both immediate and subsequent that are phenomenal.

300 Sumner Avenue.

A PROGRAM OF PSYCHIATRIC PROGRESS.

By A. J. ROSANOFF, M.D.,

KINGS PARK, N. Y.

KINGS PARK STATE HOSPITAL.

In the domain of psychiatry progress has always lagged behind that of other domains in medicine. When medical science and practice had already begun to show the influence of the Renaissance and even in the early part of the seventeenth century, when the new era had been heralded by the publication of William Harvey's discovery of the circulation, the treatment of the insane was still in the hands of the clergy and consisted of exorcisms and disciplinary measures. Later, when the care of the insane had passed largely into the hands of laymen, as a problem of public protection and of charity,

their treatment, carried out mostly in almshouses, still consisted of hardly any measures other than custody and restraint. Gradually, first here and there, later more generally, the care of the insane came to be recognized as a medical problem and from this origin may be traced the growth of psychiatry as a branch of medicine and the introduction of more rational, and therefore more humane, methods of treatment.

Thus, as insanity came to be regarded as a group of diseases to be cured, the course of psychiatry became dominated by the traditional spirit of medicine, and in this country it manifested itself mainly in a movement from county care, *i.e.* almshouse care, to State care, *i.e.* hospital care. One of the most important documents in the history of psychiatry in this country, a report under date of March 29, 1834, made to the New York State Legislature by a special committee, shows in a most striking way how much that movement owes to medical influence; in it we read: "It is now satisfactorily established that diseases of the mind yield even more readily to medical treatment than those of the body, and that in at least nine-tenths of the cases of insanity the patient may be restored to the full enjoyment of his mental faculties by the early application of judicious medical treatment." At that time, however, general medicine was again leaving psychiatry far behind, having already begun to feel the influence of a new ideal, the ideal of prevention. To-day if one were asked the question, What is the most significant advance made by medicine in the past twenty-five or thirty years? his answer would surely have to be, The advance in the knowledge of prevention of disease.

To take a concrete instance, that of typhoid fever, no one will question the fact that the suffering and average mortality of that disease have been very materially reduced by the modern dietetic treatment, hydrotherapy, skillful nursing, and perfection of surgical technique in dealing with such complications as hemorrhage and perforation. But no well informed person would measure our greatest progress in the struggle against that disease by the improvements that have been made in its treatment, but rather by the statistical estimates of the thousands of cases which have been entirely prevented, that is to say, which have not occurred but which would have occurred were it not for the modern sewage disposal plants, water filtration plants, sanitary management of dairies, and the practice of protective inoculation.

The recognition of the vast possibilities of prevention is due, it need hardly be said, to Edward Jenner, who, by his discovery of vaccination, created a new and higher aim for medicine, nowhere better expressed than in his own aphorism, "The duty of the physician is, first, to prevent disease, failing that to cure disease, failing that to prolong life and relieve suffering." To-day it may well be said that Edward Jenner "builded better than he knew," for the very direction of medical progress has changed with the recognition of prevention as the great goal of medicine.

Only in the past five or six years the ideal of prevention has begun to make itself felt in psychiatry, due mainly to an acquisition of a clearer knowledge of the nature and causes of mental disorders; and thus the old and unrealized hope of cure is being largely supplanted by the more practical hope of prevention: *the problems of psychiatry are becoming problems of public health.*

The position of psychiatry is peculiar in that the application of its scientific discoveries is, far more than applied science in other domains, dependent on legislation. The existing laws pertaining to insanity, even in the most progressive states, have not yet felt in full measure the influence of the new ideal of prevention. Although to them is due the great progress that has been made in the care of the insane heretofore, the time has come for them to be amended in important particulars, if the possibility of their becoming obstructions instead of aids to further progress is to be avoided.

The object of this paper is to present the results of a critical examination of the constitutional provisions and laws of the State of New York, a discussion of their effects on the problems of the care of the insane, and suggestions of changes and amendments which would make the laws again a power for progress and betterment. The present time is selected for making these suggestions owing to the unusual opportunity of accomplishing something, which is offered by the coming constitutional convention.

Although confined to the State of New York, this discussion cannot fail to have a bearing on the same problems in other states.

Legal Provision for the Insane.—The constitution provides for the establishment of "a state commission in lunacy which shall visit and inspect all institutions, either public or private, used for the care and treatment of the insane (not including institutions for epileptics or idiots)". (Article VIII, Section 11.) The insanity law states: "The commission is charged with the execution of the laws relating to the custody, care and treatment of the insane, as provided in this chapter, not including feeble-minded persons and epileptics as such and idiots." (Article II, Section 3). "The superintendent of a state hospital, on filing his written certificate with the commission, may discharge . . . a patient who, in his opinion, is a dotard, not insane." "A poor and indigent patient discharged by the superintendent because he is an idiot, or a dotard, not insane, or an epileptic, not insane, or because he is not a proper case for treatment within the meaning of this chapter, shall be received and cared for by the superintendent of the poor, or other authority having similar powers, in the county from which he was committed." (Article IV, Section 94.)

It is plain that those who framed these laws aimed at so limiting the term "insanity" as to exclude various mental disorders for which provision might be made in county almshouses or under the state board of charities. It was done at a time when even competent authorities held that there was an essential difference between "insanity" and other mental disorders. Eventually, however, medical men came to realize that the term "insanity" was so vague as to be incapable of definition; attempts to define it have, accordingly, been given up, but it is not so easy to give up its use altogether, and we find but too commonly, especially in criminal cases, one expert alienist diagnosing hopeless insanity where another, basing his conclusions on precisely the same data, can discern nothing but full clarity of mind.

The law, as is often apt to be the case, has been more practical. Although it has employed and still employs the term "insanity," it always clearly implies a special and limited meaning, by no means the same in all cases, but strictly relevant to the

special legal procedure for the purpose of which it is employed. Thus the law may declare a person to be insane and therefore *incompetent* to manage his own affairs; or it may declare one to be insane and therefore *irresponsible* in a criminal action; or again it may declare one to be insane and therefore of *limited testamentary capacity;* or finally it may declare one to be insane and therefore requiring *commitment* to an institution; but the law does not and cannot simply declare a person to be insane in a general way without clearly implied relevancy to a particular legal action.

In spite of the clarifying influence of the legal point of view, the mere use of the term "insanity" in legal diction has been the cause of much confusion and harm; the reason being that very few lawyers, let alone physicians and laymen, realize the lack of definition of that term, but all are apt, on the contrary, to attribute to it a special significance largely dependent on personal equation. It would seem desirable, therefore, to eliminate from the law this equivocal term and to substitute for it an expression equally convenient, as being of similar general application, yet preferable, as being less subject to inaccurate interpretation under the bias of personal equation: we have in mind some such expression as "disorder of mind" or "mental disorder."

The reader may ask, What special harm has resulted from the use of the term "insanity?" What special benefit is to be expected from substituting for it the expression "mental disorder"?

An attempt to answer fully the first question would be out of place here, as the general discussion of medicolegal problems is not within the scope of this paper; we shall therefore limit ourselves to a discussion of the prejudicial effects felt by the system which has been organized by the State for the care of the "insane".

The spirit of the great series of New York State care acts from 1836 to 1896, which were destined to become models for legislation throughout the land, that spirit, correctly interpreted, contemplated complete state care for all cases of disorder of mind, whether inherited or acquired, chronic or acute, curable or incurable, all under the control of a commission so constituted and endowed with such powers as to insure, medically the most competent, legally the most fully justified and protected, and from a lay standpoint the most economical care of all cases. Those who are familiar not only with the laws but also with the history of their enactment know very well that such "jokers" as pertain to the "feeble-minded", "dotards", and "not proper cases for treatment" have remained but as features of a compromise in the struggle for state care against formidable opposing forces representing certain special or local interests.

Owing to these "jokers" the spirit of the New York State care acts remains to-day unrealized. Every county almshouse is partly filled with cases of arteriosclerotic dementia, senile dementia, terminal stages of dementia præcox; penal institutions throughout the State are partly filled with all types of psychopaths and with cases of constitutional inferiority; for years practical necessity has caused many inmates in institutions for the feeble-minded and for the epileptic to be kept uder restraint not only without proper legal sanction but also without the control or supervision of the State Hospital Commission,—these institutions being under the State Board of Charities,—because these inmates, though most unmanageable by reason of chronic or recurrent mental disorders, are "not insane within the meaning of the statute"; and, last but not least, many thousands of cases of homeless wanderers, petty criminals, chronic drunkards, and public prostitutes, who are such by reason of manifest mental disorders, remain at large and unprovided for, a menace to the health and property of the commonwealth, an influence for the moral corruption of children, a source for the replenishment, whether legitimately or illegitimately, of the mass of neuropathic humanity; these being at large mainly because there is no room in the institutions under the State Board of Charities and because, again, they are "not insane within the meaning of the statute".

The reader may be interested to learn how this vague phraseology of the law may affect patients, not only to the extent of preventing them from being received in institutions under the State Hospital Commission, but also to the extent of forcing their discharge in spite of a perfectly valid legal commitment. An incident which occurred in the summer of 1914 and which affected hundreds of patients at this hospital alone, affords an illustration of such an effect.

In the latter part of May the hospital was notified by the commission that, owing to the failure on the part of the legislature to reappropriate, according to usual custom, the hospital board moneys, large retrenchments would have to be made in order to avoid a deficit at the end of the fiscal year. Shortly afterwards a second letter was received from the commission urging the hospital authorities to go over the cases on the various services with a view to selecting from among them such as may be discharged or paroled as being either "recovered" or "not insane within the meaning of the statute", thus facilitating the reduction of the budget for maintenance. The commission was not actuated by any suspicion that there might be cases improperly detained at the hospital, but merely by financial stringency. It is significant also that the commission called special attention to the "joker" in the law which we have already quoted and which for the reader's convenience we will here quote again: "A poor and indigent patient discharged by the superintendent because he is an idiot, or a dotard, not insane, or an epileptic, not insane, or because he is not a proper case for treatment within the meaning of this chapter, shall be received and cared for by the superintendent of the poor, or other authority having similar powers, in the county from which he was committed". (Article IV, Section 94.)

What happened following the receipt of these letters from the commission has been related in our annual report, from which we would quote the following: "251 patients were discharged as recovered, making the recovery rate, based on direct admissions, 22.37 per cent, that of the preceding year being but 19.16 per cent. A similar increase is to be noted in the total number of cases discharged as either recovered, or much improved, or improved, which amounted to 41.28 per cent as compared with 34.10 per cent of the preceding year. We are not inclined to attach much significance to this apparent increase in the recovery rate. As already hinted in our last year's report, present day statistics of recoveries are vitiated by the intrusion of the legal point of view, whereby their value from a medical point of view is im-

paired. As all know, it is the frank policy of all institutions to discharge, as 'recovered', cases of imbecility, constitutional inferiority, epilepsy, senile dementia, organic brain disease, etc., upon the subsidence of the acute psychotic manifestations which have arisen in these cases and constituted the indications for commitment. . . . The same may be said of the increase in the number of cases discharged as 'not insane', and in this connection attention may be called to the significant fact that 27 cases discharged as 'recovered' and 6 cases discharged as 'not insane' were so discharged into the custody of the Department of Public Charities in the Borough of Brooklyn, it being recognized that though legally 'recovered' or 'not insane' these cases nevertheless required continued institutional care. . . . On May 31, 1914, the number of patients on parole in the custody of relatives or friends was 165; by September 30 it had reached to 324. . . . The question may well be raised whether it is wise or even justifiable for the State to shift any part of the burden of the care of the insane upon the friends of the patients or upon the county from which they came. The distinction between sanity and insanity is not a sharp one, but rather one of gradual transition, and on the borderland there are numerous cases in which judgment as between the two is largely influenced by personal equation, and the law sometimes permits different ways of handling the one and the same case. The cases which were discharged or paroled from this hospital under the stress of unusual conditions during the last four months of the year, and which under normal conditions would have been detained, were, to be sure, selected with care and with a view to minimizing the danger to the patients themselves and to society; but it is practically self-evident that as the number of parole cases becomes larger there is a very considerable increase in danger in spite of the exercise of all ordinary care that can be given. And, while we refer here to the immediate danger from suicide, violence, homicide, incendiarism, etc., . . . the more remote, though no less certain, danger of unrestrained propagation and transmission to future generations of tendencies toward insanity . . . must be borne in mind as a matter of much greater moment. . . . The return of patients to the country as 'not insane within the meaning of the statute' is, of course, less objectionable than their discharge to the custody of friends, so long as their return to the county means a continuance of segregation from those of the community at large, but it is, nevertheless, a step backward and does not commend itself to those who are familiar with the conditions in the past which led to the movement for the abolition of county care and the development of State care."

There remains for our consideration the second question, What special benefit is to be expected from substituting for the term "insanity" in the legal phraseology the expression "mental disorder"?

To this our answer is that such a change alone would probably accomplish very little, but that such a change together with the elimination of the above discussed points pertaining to feeble-minded persons, idiots, epileptics, and dotards "not insane" would render at last possible the complete realization of the spirit of the New York State care acts by opening the doors of the State hospitals on equal terms and without discrimination to all legal residents of the State suffering from mental disorders and requiring custody, care, or treatment; the great problem of the prevention and management of mental disorders would then be entirely in the hands of the body that is most capable of coping with it, the State Hospital Commission; and there would no longer be a waiting list of patients vainly seeking admission.

Legal Provision for Public Charities.—Although our concern is only with matters which are or should be under the control of the State Hospital Commission, there is, under the existing circumstances, so much overlapping of the domain of the commission by the powers and activities of the State Board of Charities, and of the poor law authorities of the various counties and municipalities that the law pertaining to public charities will have to be at least briefly considered.

In the first place, it follows, as a corollary from what has been said above, that in order to place all cases of mental disorder of whatever kind under care of the State Hospital Commission those parts of the law must be amended which place the control of the institutions for idiots, epileptics, and the feeble-minded in the hands of the State Board of Charities.

In the second place, we find in the State charities law an inaccuracy of diction analogous to that found in the insanity law and, it seems to us, one that is equally fraught with possibilities of confusion and harm, namely, the use of the very term "charities."

It may well be questioned whether the people of the State who avail themselves of the benefits of institutions established and maintained by themselves may any more properly be regarded as objects of charity than, say, the beneficiaries of mutual insurance companies or of fraternal organizations.

It may also be questioned whether the taxpayers who support the so-called charitable institutions, directly or indirectly—which includes all residents of the State—can properly be said to be making charitable donations when the fact is that these "donations" are in the shape of taxes constituting a legally established liability and having no reference whatever to the presence or absence of any charitable inclination in the "donor."

The public provisions for the sick in hospitals, for orphans and for the aged and infirm in asylums, for the blind and deaf in special schools, for the irresponsible in State institutions, and even for those who have been impoverished through unemployment in hard times, it seems to us, are more properly to be considered as forms of social insurance organized by states, counties, or municipalities for their own benefit, just as schools, roads, and bridges are built, the police and the militia are maintained, etc. No one would assert that a person who sends his child to a public school to receive free tuition, or who walks across the Brooklyn Bridge without paying a toll, or who has occasion to call for and receives protection from the police, is an object of charity, in spite of the fact that he is the recipient of benefits provided by vast expenditures of public funds.

Schools, orphan asylums, old men's homes, hospitals, etc., may, indeed, be organized as charities, but such is, properly speaking, the case only when they are supported by the voluntary contributions of private individuals or corporations. And here it is safe to add that wherever in a democratic community a need exists for private charities for such purposes such need is due to imperfect organization

or misgovernment. And it is equally safe to add, further, that wherever a community neglects to make public provision for such needs of its citizens and depends to any considerable extent upon the charity of private individuals or corporations, these needs invariably remain improperly and inadequately provided for.

As a matter of fact, persons who, by reason of mental defect or disorder or by reason of physical disease or infirmity, are unable to support themselves, are fed, clothed, and sheltered by others, more fortunately situated, whether organized means for providing their food, clothing, and shelter exist or not; and when communities establish institutions for dependents it is not so much from motives of charity as from motives of prudence, as every one recognizes that any large problem can better be solved by means of an organized system than by the occasional sporadic efforts of individuals; or, in more pertinent language, the interests of public peace, safety, and economy, rather than impulses of charity lead states, counties, and municipalities to establish such institutions.

But here again the reader may ask, What special harm results from the use of the term "charities" in this connection, granting even that there is no reason, other than euphony, for retaining it?

In our opinion, paradoxical as it may seem, the term "charities" tends to defeat the very purpose for which it is employed, owing to the implied misrepresentation of facts and motives. When taxpayers or their representatives are asked for appropriations for "charities" the mere regard for their own interests, or those of their constituents, which is both natural and legitimate, dictates a restriction of any altrustic impulse within the limits of "moderation"; and if they do not happen to be charitably inclined they may even resent being thus approached. Indeed, as it is generally not the taxpayers themselves but their repesentatives in legislature that are thus approached, the moral right may be questioned of their yielding to an outburst of generosity in response to an appeal for charity by dipping not into their own pockets but into the people's treasury and in that manner disposing of public funds; it is but a truism of democracy that public funds can properly be used only for the welfare of the general public and not for any special class, even though that class may be the class of dependents.

Moreover, while the use of the term "charity" in this connection carries the false implication of a charitable motive, the true motive of public welfare thereby fails to be brought to the attention of the representatives of the taxpayers. It is not surprising, under these circumstances, that the institutions for the feeble-minded, epileptic, and other defectives are inadequate, that there are long waiting lists of applicants for admission living at large, a constant and growing menace to the public welfare.

Let not the reader conclude that we would eliminate charity from our lives, for nothing is further from our mind. Our contention is merely that charity is truly such when it is not strained, when it blooms of itself as a personal virtue and not when discharged as an ordinary civic duty in the shape of payment of taxes. When all that public welfare demands has been accomplished by communal action, there will still be enough left for the constant exercise of charity, more than enough, we fear, owing to its rarity.

As to the euphony of the term "charity," it may possess that quality for those who give, but for those who receive, unfortunately, it rather carries a stigma, far more often than not, without such stigma being actually deserved. Just as, to remove an unjust stigma, it was found desirable to take out of the county almshouses all the insane who were kept there as paupers, just as it was found desirable, for a similar purpose, to substitute "state hospitals" for "lunatic asylums," so it would be desirable to replace the "State Board of Charities" by say, a "State Board of Administration."

A Discussion of Some Objections.—The reader will have realized ere this that this program of psychiatric progress, if carried out, would result in a great extension of the duties and powers of the State Hospital Commission; the idiots, the feeble-minded, the epileptics, the dotards would be transferred from the state department of charities and from the county almshouses to the care of the commission; thousands of persons suffering from mental disorders who are now at large, being considered "not insane," would be received in institutions as additional cases to be cared for by the commission. In brief, the standards of care would be raised, the number cared for would be increased, the budget for construction and maintenance would be swelled enormously.

On our part, we admit that before we can expect this program to be favorably considered we must show, firstly, that public welfare would be sufficiently benefited by it to justify its adoption; secondly, that it would not be contrary to the interests of economy of public funds, and thirdly, that a feasible plan of financing could be devised and that it is not merely an Utopian scheme: the burden of proof is upon us.

The benefit that would be gained for public welfare by the sequestration of many persons who are now at large would be mainly in the shape of greater protection against vice and crime than even the best governed communities have hitherto enjoyed.

The relationship which exists between mental disorders and *prostitution* has been most carefully studied by a special commission created for that purpose by an act of the House of Representatives of the State of Massachusetts. We would quote the following from their highly interesting official report[2]: "The women examined were in three groups: young girls under sentence in the State Industrial Schools for Girls, the House of Refuge, and the Welcome House; those just arrested and awaiting trial in the Suffolk House of Detention in Boston; women serving sentence in the State Reformatory for Women, the Suffolk County Jail, and the Suffolk House of Correction.

"These three groups represent the young girls who have just begun prostitution, the women plying their trade on the streets at the present time and the women who are old offenders. The houses of prostitution, lodging houses, hotels and cafés named by these women as the places where they plied their trade are the same as those noted by the field investigators employed by the commission.

"The Binet tests were applied to 289 of the 300 women examined, and other psychological tests were used in doubtful cases.

"Of the 300 prostitutes, 154, or 51 per cent., were feeble-minded and 11, or 3 per cent., were insane. All doubtful cases were recorded as normal. The mental defect of these 154 women was so pronounced and evident as to warrant the legal com-

mitment of each one as a feeble-minded person or as a defective delinquent. At the Massachusetts School for the Feeble-Minded there are an equal number of women and girl inmates, medically and legally certified as feeble-minded, who are of equal or superior mental capacity.

"The 135 women designated as normal as a class were of distinctly inferior intelligence. More time for study of these women, more complete histories of their life in the community and opportunity for more elaborate psychological tests might verify the belief of the examiners that many of them also were feeble-minded or insane.

"Some of the women seen at the Detention House were so under the influence of drugs or alcohol as to make it impossible to study their mental condition. Others at the Detention House and in the prisons had used alcohol to excess for years, and in the time available it was impossible to differentiate between alcoholic deterioration and mental defect. These drunken, alcoholic, and drug-stupefied women were all recorded as normal.

"Of the 135 women rated as normal, only a few ever read a newspaper or book, or had any real knowledge of current events, or could converse intelligently upon any but the most trivial subjects. Not more than six of the entire number seemed to have really good minds.

"It has long been held that prostitution always has existed and always will exist, and that all remedies will be ineffective and of no avail, because it represents a variation of the most fundamental human instinct.

"Recent studies of prostitution and prostitutes in other cities, States and countries, and, in connection with this investigation, the study and analysis of 300 prostitutes individually examined for the commission, the observation of prostitutes and prostitution, and of the immoral young girls who have not entered prostitution in cities and towns all over the State, have convinced the commission that this evil is susceptible of successful attack and treatment. The fact that one-half of the women examined were actually feeble-minded clears the way for successful treatment for this portion of this class. The mental status of the prostitutes under arrest should be determined, and such of them as are found to be feeble-minded or defective delinquents should be placed under custodial treatment. Thus would these women themselves be saved from an evil fate, pimps and procurers would lose their willing prey, and a non-self-supporting class who find in prostitution their only way of earning a living would be taken out of the community.

"The recognition of feeble-minded girls at an early age in the public schools, and proper provision for their protection in the community or custodial care in an institution, would prevent much of the observed immorality among young girls and the resulting temptations to boys. Precocious sex interests and practices are well-known symptoms of feeble-mindedness."

Equally striking is the evidence of the relationship which exists between mental disorders and *crime*. As regards feeble-mindedness alone, for instance, Goddard[7] cites the following statistics of percentages of defectives found in various reformatories and institutions for delinquents by the systematic application of Binet tests: Rahway Reformatory, New Jersey, 46; Geneva, Illinois, 89; Ohio Boys' School, 70; Ohio Girls' School, 70; Virginia, three reformatories, 79.

The statistics of the United States Census pertaining to insanity and crime are also of interest in this connection.

The States of this country may be divided into two groups according to the number of inmates in insane hospitals in proportion to the general population. Since, for the present purpose, this is done to facilitate the study of the relationship which exists between crime and insanity, it would seem best to take into consideration only the male population at large and the male asylum and prison inmates: crime is not nearly so common, whether as a neuropathic manifestation or otherwise, among women as among men, the counterpart among women being sexual immorality, prostitution, illegitimacy, etc.

The first group of States, comprising Alabama, Arkansas, Colorado, Florida, Georgia, Idaho, Louisiana, Mississippi, New Mexico, North Carolina, North Dakota, Oklahoma, South Carolina, Tennessee, Texas, Utah, West Virginia, and Wyoming, has a total male population 10 years of age or over of 9,705,527; each of these States has less than 200 male asylum inmates per 100,000 of the male population 10 years of age or over, the average for the entire group being 140.9.

In this group of States the number of inmates in prisons, penitentiaries, jails, and workhouses, not including juvenile delinquents, is 31,290, *i.e.* 322.4 per 100,000 of the general population 10 years of age or over.

The second group of States, comprising Arizona, California, Connecticut, Delaware, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, Missouri, Montana, Nebraska, Nevada, New Hampshire, New Jersey, New York, Ohio, Oregon, Pennsylvania, Rhode Island, South Dakota, Vermont, Virginia, Washington, and Wisconsin, has a total male population 10 years of age or over of 27,190,148; each of these States has more than 200 male asylum inmates per 100,000 of the male population 10 years of age or over, the average for the entire group being 304.7.

In this group of States the number of inmates in prisons, penitentiaries, jails, and workhouses, not including juvenile delinquents, is 71,482, *i.e.* 262.9 per 100,000 of the general population 10 years of age or over.

The contrast between the two groups of States as regards the relative number of prisoners is sufficiently striking as revealed by the census statistics. But it is probable that the excess of crime in the first group of States is but partly revealed in these statistics; for it seems reasonable to assume that the facilities for the detection and prosecution of crime are in these States, like other social institutions, inferior as compared with those of the second group of States, so that a greater amount of crime remains undetected and unrepresented in the statistics of penal institutions.

However this may be, it seems certain that the inadequacy of the provisions for the care and custody of cases of mental disorder in the first group of States, regarded from its financial aspect alone, does not carry with it the advantage of economy, for what may be saved in expenditures for the maintenance of the insane is lost in increased expenditures for the maintenance of convicted criminals; it is, indeed, not unlikely that the loss is far greater than the saving.

To give the reader a more direct view of the evidence showing a relationship between crime and mental disorders we could do no better than to quote

from a report prepared by Dr. Anne Moore, in which several pages are devoted to a consideration of the crime of arson'.

"Arson is a common crime among the feeble-minded. . . . Many times thousands of dollars' worth of property are destroyed and many lives endangered before legal proof of guilt is established. On conviction these persons are often committed to penal institutions, only to be paroled and set free to repeat the crime; or they are left to serve long sentences which on their release do not act as a deterrent. The Fire Marshal of New York City tells me that a sufficient number of cases of pyromania have come to his attention to fill a special institution. Two cases have come to my knowledge in which feeble-minded children have set fire to the clothing of other children with fatal consequences.

"Between the dates of February 1, 1910 and July 12, 1910, sixteen fires occurred in the district bounded by Fifth and Lexington avenues and 108th and 119th streets, all in twenty-family, five-story tenements, and all of similar incendiary origin. These fires were traced to a feeble-minded youth who had no motive for the deed except a desire for excitement. When he visited one of the buildings to deliver goods his method was to light a bundle of papers which he had previously saturated with kerosene from a bottle which he carried with him, and leave them in the hallway, in a corner of the stairway, or in the cellar. He was caught and convicted on the sixteenth fire. He was declared insane and is now confined in the Central Islip State Hospital.

"A feeble-minded man, 25 years of age, started 45 fires within three months. The loss was estimated at a quarter of a million dollars. He usually left something burning in the airshaft or wood-bin. At his trial he was declared sane and was sent to Elmira. After 13 months he was released on parole and won his absolute release.

"A feeble-minded boy, living in Massachusetts, set fire to his grandfather's house. He saved himself by jumping from the upper window into a cherry tree. Afterwards, he set fire to a stable in Gloucester, Mass., and was sent to a reform school for two and a half years. After his release he set on fire, one by one, a row of houses owned by different clergymen, called 'holy row.' Later he burned a house belonging to the father of the district attorney, was caught, and convicted. He spent four years in Charlestown Prison. He became religious and was paroled on condition that he go to another State. He came to New York and for a time was under Mrs. Booth's care. Afterwards he set fire to a barn and to the Bayside Yacht Club. He was caught and convicted. He is now in Sing Sing.

"What this means in money may be gathered from following the evidence and proceedings in any case of arson, a common crime among mental defectives.

"(1) A building is set on fire with attendant danger to its dwellers, and loss of property to them and the owner.

"(2) The fire department is called out. Usually six companies, involving one battalion chief, 72 men, 4 engines, and 2 trucks, the police reserves, usually about 20 men, and an insurance fire patrol wagon with an officer and 10 men, respond to an alarm.

"(3) The offender is arrested by a police officer, after examination of material witnesses by a fire marshal.

"(4) After being taken to the station house the incendiary must go before the magistrate; and if brought to trial, with its attendant delays, much time of many different salaried officers is consumed as well as that of the material witnesses.

"(5) After conviction and before sentence is passed a probation officer may be asked to look into the history of the case, which will take at least a week. The sentence may be any length of time, up to 40 years.

"All this expensive machinery need not have been used in the case of feeble-minded incendiaries if they had been cared for in institutions at the proper time.

"That the segregation of defectives costs money is remembered; that it saves money is often forgotten. The initial cost of segregation would be great but the saving effected by correcting our present lax methods would be greater. As tax bills are not itemized the ordinary citizen does not realize that he is at present paying for the unrestrained presence of the feeble-minded. An added tax for their segregation would be an apparent rather than a real increase, for through segregation of defectives, the number of criminals, the number of prisoners, the cost of trials, the demand upon public and private charity would be decreased; and as control of hereditary conditions resulted in decrease in the number of defectives, and training rendered many of them self-supporting, the expenditure necessary for their maintenance would from year to year grow less. The feeble-minded at large are as dangerous, if not more dangerous, than persons suffering from contagious disease. No consideration of cost, of parental affection and responsibility, or of personal liberty, should be allowed to weigh against public safety."

We believe all will agree with us that the policy of dealing with vice and crime, which has been followed by States hitherto almost exclusively, on the principle of locking the stable after the horse is gone, can be improved upon. It will be found safer, more economical, and wiser in every way for every State to bring under control not only all actual criminals, but also, as far as possible, all potential criminals. And if anything is true in psychiatry it is that every person who has a mental disorder is a potential criminal.

But the greater protection and more efficient dealing with the problems of vice and crime are not the sole benefits to be gained for the welfare of the public by the adoption of this program of psychiatric progress. As we have already hinted in the introductory remarks, the time has come for psychiatry to join the new general trend of medicine, to be guided by the new ideal, the ideal of prevention. The most important cause of mental disorders being heredity, the most effective means for their prevention are those that would stop the transmission to future generations of the neuropathic traits of the unfit of this generation. Of the means that have been suggested to accomplish this end, legal restriction of marriage, surgical sterilization, and segregation, only the last mentioned has proved likely to be both efficient and generally acceptable to public opinion. Thus the increase in the number of State hospital inmates as contemplated in our plan becomes an act of public health, of mental hygiene. For, just as the New York State Department of Health is able to say, "Public health is purchasable: within natural limitations any community can determine its own death rate,"

so we are now in a position to say, "*Mental health is purchasable: the prevalence of mental disorders in the coming generations can be reduced with the aid of dollars and cents spent for segregation in this generation.*"

It remains for us to show that for this program a feasible plan of financing can be devised. We believe, indeed, that the entire program could be put in operation without any increase whatever of legislative appropriations.

As already stated, the benefits that hospitals and asylums afford are to be felt not only by the present generation, but also, and probably even to a greater extent, by generations to come. Large enterprises, whether of governments or of private corporations, are capitalized with the aid of public loans of long term, while capital that is otherwise available is used merely for current expenses of operation. Thus public schools, highways, canals, railroads, telegraph and telephone systems, manufacturing plants, power plants, mining equipments, etc., have been built with the aid of capital derived from issues and re-issues of long term bonds; and no one has questioned the equity of thus assuming debts to be paid by future generations. It is a curious fact that the establishment of institutions for neuropathic persons forms almost everywhere a unique exception. No State as yet possesses anything like adequate facilities for the care of its neuropathic persons. Yet every State could, without any added expenditure, easily double or treble its facilities with the aid of bond issues and thus make funds that are now expended for construction available for the maintenance of the increased number of its wards. In New York State alone the total legislative appropriations of special funds for new construction in the State hospitals and charitable institutions in the year 1912 was $3,210,304; while the appropriations desired for similar purposes at the 1913 session of the legislature were $5747,849.50.[5]

If the present generation could have the choice between having to pay for the maintenance of a large number of neuropathic persons and having merely to pay off the matured bonds issued by a preceding generation for the establishment of facilities of prevention, there would be no question as to its preference; but it has not that choice, for past generations acted against its preference. And should the present generation decline to incur a bond indebtedness to be paid off in the future and thus allow neuropathic persons to remain at large for lack of room in the institutions, its action would be similarly against the preference of future generations.

No other enterprise that the State might undertake could more fully justify the issuance of long term bonds than that of the construction of adequate facilities for the prevention, treatment, and custody of cases of mental disorder.

TUBERCULIN THERAPY,

ITS PRESENT IMPERFECTIONS AND FUTURE IMPROVEMENTS.*

By FRANCIS M. POTTENGER, A.M., M.D., LL.D.,

MONROVIA, CAL.

MEDICAL DIRECTOR, POTTENGER SANATORIUM FOR DISEASES OF THE LUNGS AND THROAT; PROFESSOR OF DISEASES OF THE CHEST, MEDICAL DEPARTMENT OF THE UNIVERSITY OF SOUTHERN CALIFORNIA.

I DESIRE to discuss a number of different things rather than some single phase of tuberculin therapy. I am not a laboratory worker. My work has been almost exclusively clinical. What I know about laboratory work comes from study and association with those who work in the laboratory, and an attempt at the clinical application of laboratory methods and products.

Tuberculin has been in use for nearly a quarter of a century, and it seems strange that after all this time there are no definite, generally accepted ideas about it. This is partly due to a misunderstanding of the remedy and what is to be expected of it. In the first place, too much is demanded of tuberculin. We demand that it do the impossible. It may not immunize a guinea pig; it may not produce complete immunity; it may not cure experimental tuberculosis; and yet, it may be of value in the healing of human tuberculosis.

In order to understand the action of tubercle vaccines, their specific immunizing and specific stimulating properties must both be borne in mind. Tubercle vaccines are made up of many substances, such as proteins, fats, and toxins, which produce specific antibodies against themselves, and which, when administered in the proper proportions, we are led to believe, produce more or less immunity against the tubercle bacillus. Many of these substances when injected produce a specific stimulation of the foci of infection. It is to this specific focal stimulation that the healing is probably largely due. Therefore, while the various vaccines with which we have been working have failed to produce a high degree of immunity in experimental animals, except in rare instances, this must not be interpreted as meaning that the remedies have no healing properties. Clinical observation comes to our rescue at this point and prevents the wrong conclusion being drawn; for definite focal stimulation and healing has been seen to follow the administration of these same preparations which have failed to produce a high degree of experimental immunity.

Its most ardent supporters admit that tuberculin is far from a perfect remedy; but, if anyone will watch the clinical results of those who use it most successfully, he must see that sufficient unquestioned results have been obtained to show that tuberculin does have value in the healing of tuberculosis. The results which tuberculin can produce must be judged by the very best that have been obtained; whether or not it is a practical remedy and can be used generally, is a different question. If a given clinician or many clinicians obtain results with tuberculin which others cannot produce, it does not necessarily mean that tuberculin is at fault. It is more likely the physicians who are at fault. In my personal experience in the clinical use of tuberculin in tuberculous laryngitis, I have had exceptional opportunity to prove its worth; and I am

*Read before the first annual meeting of the American Society of Immunologists, Atlantic City, N. J., June, 1914.

able to say that I expect practically every case of tuberculous laryngitis in patients in whom the pulmonary disease is in an early stage, or, if advanced, not active or only slightly so, to become arrested. I have never seen such results without tuberculin. I am so positive of the clinical value of tuberculin in my own practice, that I would not feel that I was doing justice to my patient if I withheld it. On the other hand, I see many men whom I feel are doing harm in using it. It is not the remedy which is successful in one instance and failing in the other; the difference is in its administration.

I desire to refer to the often quoted fact that tuberculin fails in experimental work. There are many things to consider. There is a difference between guinea pigs and rabbits; a difference in different guinea pigs; a difference in different cultures employed; a difference resulting from differences in media, one culture producing a tuberculin differing in the various constituents from that produced from another culture. There is also a great difference in the method of administering the tuberculin to the animals.

Aside from this experimental tuberculosis, at least that which is produced in guinea pigs and rabbits, is tuberculosis on virgin soil, the animal not having developed any immunity from previous inoculation. Naturally such a tuberculosis is rapid in its course and shows little tendency to heal. Tuberculin might fail absolutely in the production of healing or in protecting these animals and still be of great value in the treatment of the chronic form of tuberculosis as we find it in human beings, particularly in adults and children after the first year or two of life, who have taken into their bodies tubercle bacilli so long that they have developed a marked resistance to the disease.

If we take these facts into consideration we see that many difficulties have operated against the production of satisfactory or even constant results. We have not only failed to understand tuberculin, we have failed in its application. Improvements in its use depend upon better observations by the clinician. We can not produce the best results in the use of any remedy by routine methods; yet, there is a tendency for clinicians to treat all tuberculosis alike. One patient reacts differently from another, and it must be understood that a dose suitable for one patient may not be suitable for another. If we give a dose of tuberculin once a week, twice a week or once a month, or twice a month, or if we give a set dose at each administration, we are administering tuberculin but not treating tuberculosis in the most intelligent way. Clinicians must study carefully the question of dosage, the intervals between doses, and the manner in which these differ according to the different pathological conditions present if they are to obtain better results and make progress. To make my meaning clear, I would not treat tuberculosis of the eye the same as I would an incipient pulmonary lesion; nor would I treat the latter as I would an advanced lesion with tendency to activity. Individualization must be carried on with regard to both the patient and the pathological lesion.

As to reaction, the same reaction is not obtained with different preparations; for example, with B.E. as T.R. or O.T. The same reaction does not occur in one patient as occurs in another. Variations must be expected. If progress is to be made in the specific treatment of tuberculosis, improvement must be made both in the laboratory productions and their clinical application. It has been accepted for the past few years that tubercle vaccines are all the same qualitatively, and that the real difference is in their administration. We now know that there are also essential differences in the constituent portions of the various preparations, that the proteins, the fats, and the toxins are present in different amounts and different degrees of availability. The reaction differs according to the varying amounts of the different constituents which the vaccine contains. We are not dealing with a certain standardized product. I believe, however, that if we can produce vaccines which approach a definite standard, that we will have more uniform and more certain results. Such work as that of Vaughan separating tubercle bacilli into different proteins, one soluble and one insoluble; that of Much in producing the various partial antigens belonging to protein, fat, and toxin groups; that of von Ruck in the isolation of several proteins; and the proof that these constituents differ and that most of them can be made to produce antibodies specific against themselves, to my mind, is pointing the way to future improvements in the production of specific tubercle vaccines. The work of such men also shows us where some of our difficulties have been. Another source of error is in our attitude toward the laboratory. We are apt to think laboratory work is absolutely accurate. When one carefully considers the facts, he will find that laboratory work may be no more accurate than clinical work. Laboratories, no matter how carefully conducted, have their errors.

The solution of the problems of the immunization against, and cure of tuberculosis in human beings, is the province of the clinician, and he must be careful not to be misled by depending wholly on the laboratory. A man who works wholly in the laboratory should not be expected to be as accurate in his clinical observations as the clinician. His clinical interpretations would be subject to much error. Neither must the clinician be expected to do the best laboratory work. The best results in tuberculosis should be obtained by a union of forces between the clinician and laboratory man, both studying and working together. A good illustration of the danger to scientific observation when made by an inexperienced clinical observer is the following: During my visit to the laboratory of one of our greatest bacteriologists a few years ago a woman came from quite a distance to be treated for tuberculosis. He gave her an injection of tuberculin, after which she had quite a fever. He said this was a negative phase caused by too big a dose. I asked him if he did not think it was probably due to her trip since she rested at home all the time, except when coming for treatment. He replied in the negative. His view was too narrow. It needed the broadening of the clinical observer.

It is generally believed that the only way to test a scientific discovery is by approaching it with an unbiased mind. This unbiased mind as a rule proves to be a hostile mind. To prove the value of preparations such as tubercle vaccines, it is just as important to be in sympathy with the remedy and to have an interest in the disease and patient as it is to assume a critical, hostile attitude. If one's observation goes contrary to the things that are reported it does not necessarily mean that he is wrong. We must bear in mind in our study of immunity that there is very little that is not changeable or cannot be questioned.

One important point which offers hope for the future in the specific treatment of tuberculosis is that we now know that vaccines contain many important substances which help to build up a complete immunity; and further, that different preparations contain these given substances in varying quantity. It is the duty of the laboratory to produce and the clinician to test these various constituents and then see if a more perfect remedy cannot be derived. The clinician should observe more carefully than he has in the past. He has been overawed and overshadowed by the laboratory, and he has failed to make the progress that he should. He should observe every change that follows his injection himself and not depend on the laboratory to tell him of it. The clinician should test the facts produced by the laboratory, and the laboratory worker should suit his work to the clinician's needs, heeding his observations, and trying to produce something of practical value instead of continuously going over and accepting certain things as proven and unchangeable, for progress is made in medicine only by doing what has hitherto seemed impossible.

SOME DESULTORY PERSONAL OBSERVATIONS ON PERINEORRHAPHY, PUERPERAL SEPTICEMIA, AND PAIN.*

By J. MILTON MABBOTT, M.D.,

NEW YORK.

CONSULTING OBSTETRICIAN, NEW YORK NURSERY AND CHILD'S HOSPITAL.

The Proper Needle for Immediate Perineorrhaphy.

By the term immediate perineorrhaphy I mean perineorrhaphy usually within thirty-six hours, not necessarily on the first day. I wish to refer to the subject on this occasion because I know that certain supply houses still put on the market catgut sutures for perineorrhaphy already threaded into half-curved or even full-curved needles. In a paper read before the Hospital Graduates' Club some years ago I exhibited charts illustrating my ideas of the mechanics of deep sutures, and I demonstrated how difficult or impossible it is to introduce deep perineal sutures properly with anything but a long straight needle but slightly curved near the point. I stated that Emmet and Goffe had both emphasized the importance of using such a needle. Further experience and the results of imperfect or unsuccessful repair of the perineum, as observed by me during many years of service in the Out-Patient Department of the New York Hospital, have confirmed my views on this subject. On October 29 of this year I saw a pretty bad example in a patient delivered under "twilight sleep" in a New York City hospital just one month before. (On November 12 there was still a granulating ulcer in the vagina.) My paper with illustrations was published in the *New York Medical Journal* for April 14, 1900. I have nothing to add to or retract from the views there expressed. They were summed up as follows: "Make the sutures include enough tissue on both sides of the wound to exert their greatest traction in the right direction and hold the wound surfaces together in their natural relations." To do this easily a proper needle is essential.

*Read at a meeting of the Hospital Graduates' Club, November 19, 1914.

Heterogenous Vaccines in Puerperal Septicemia.

We now come to the question of vaccines. On this occasion I am not citing authorities and literature, but in this audience the statement will pass unchallenged that the medical profession has been pretty thoroughly warned not to expect much good from vaccines in the treatment of septicemia except when of the autogenous variety. I desire to report a case—very imperfectly, I regret to say—in which a brilliant result followed the use of a stock vaccine. Before doing so I may be pardoned if I endeavor to influence opinion in my favor by stating that our esteemed colleague, Dr. Francis Carter Wood, in private discussion, fully endorsed my position, recommending the use of such vaccines in urgent cases; at least until autogenous vaccines can be prepared.

Mrs. A. B., 37 years old, native of Italy, has had five previous children and several miscarriages. She has had bad leucorrhea for some years. On May 14, 1913 her husband called me up on the telephone about 8 P.M. and said the waters had broken, but the patient was having no pains; he wanted me to be where he could call me if they began. Three hours later he called me again, and responding at once I found the patient in labor at full term, and remained until the birth of the baby at 3:25 A.M. May 15 (the secundines following at 3:37 A.M.,) and for more than an hour afterwards. All examinations were made with sterile glove out of lysol solution, one-half per cent., and a bichloride solution, 1:4000 was used externally. A large amount of blood, probably forty ounces, accompanied the afterbirth. The patient suffered terribly with all labor pains until relieved by chloroform and also with afterpains; for the latter, codeine and ergot were administered with fairly satisfactory results. Septic symptoms developed on the third day. I attribute the infection to the previous condition of the cervix. On May 18 the afternoon temperature was 102° F. at 5 P.M. A dose of castor oil was followed by free catharsis and the temperature on May 19 had fallen to normal, 99° F. at 2:30 P.M. But the next day there was fever of 101° at 2 P.M. and I thoroughly explored and cleaned out the uterus with two fingers, using a douche at the same time of bichloride solution (about 1:10,000) followed by a weaker solution (1:16,000). There was very little débris but considerable odor. The next afternoon, the seventh after delivery, pulse was 88, respiration 24 and temperature 103°. I gave a vaginal douche (1:6000) and an intrauterine douche (1:12,000) at 2 P.M. On the eighth day temperature was 100.4° at 3:30 P.M. and I felt greatly encouraged. But the following day, with a pulse of 108 and respiration 26, the temperature rose to 104.2° at 2:15 P.M. There were no signs of peritonitis, or local foci of infection, and liquid diet and supporting measures, including quinine, without further local treatment, were relied upon for the ensuing twenty-four hours. We had now reached the tenth day after delivery. In the middle of the day, about 2 P.M. the patient had a very severe and prolonged chill and at 2:45 P.M. her pulse rose to 144, breathing 48, and temperature 106° F. The woman had a terrific headache, was greatly excited and exceedingly frightened, believing she was certainly going to die. I gave another intrauterine douche, employing a solution of corrosive sublimate (1:8000) followed by a weaker one (1:16,000), thoroughly drained out by posture and manipulation. I then secured a reliable stock vaccine containing seven hundred million killed bacilli, composed of four hundred million staphylococci, one hundred million streptococci, and two hundred million colon bacilli. This was injected, as I remember, into the subcutaneous connective tissue of the lower part of one side of the chest. There was some delay in finding a consulting obstetrician and failing to locate several whom I knew I secured the services of Dr. G. Ippolito, consulting obstetrician to the Italian Dispensary, who examined the patient and approved the treatment with two special recommendations: first that no more douches be given as he found the uterus perfectly clean; second that no more vaccines be used as he did not believe in them. I told him I was quite willing to follow his advice in regard to the douche, as

I had followed my treatment as far as I considered desirable, and that I was fully satisfied for the present in regard to the vaccine as I had given what I believed to be a sufficient dose, especially as the patient's temperature was now receding: but I told him frankly that otherwise I would not have been governed by his advice without further consultation. The temperature at 3:45 P.M. had fallen half a degree and, when Dr. Ippolito saw her with me at 6:20 P.M., a whole degree, to 105° F. Dr. Ippolito recommended ergot, digitalis, continuing bromide and chloral, etc. At 9:45 P.M. the temperature was down another half degree and the patient was resting comfortably. On the following day the pulse, respiration and temperature respectively were: P. = 84, R. = 24, T. = 100.6°, at 10:30 A.M.; P. = 78, R. = 20, T. = 99.2°, at 4:15 P.M.; P. = 78, R. = 22, T. = 99°, at 9:40 P.M.

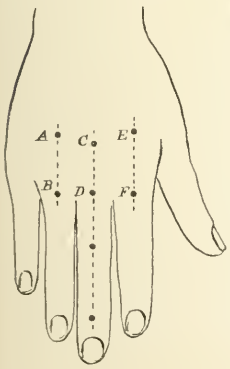
On Monday, May 26, forty-eight hours after the crisis the woman's pulse was 72, respiration 18, temperature 99° F. and thereafter the temperature ranged from 99° to 98° F. The woman made an uneventful recovery and was able to nurse her baby.

I have never lost a patient from sepsis in private practice, nor in fact under any circumstances where the patient has been under my own care exclusively. But I shall always be glad that a vaccine was available in addition to all other remedies in this spectacular case.

The Need of Better Judgment in the Infliction of Pain and Better Facilities for Its Relief in Medical, Surgical and Obstetrical Practice.

In an article on "Improved Methods of the Twentieth Century Doctor," in the New York *Tribune*, Sunday, September 24, 1905, it was observed that "patients who now fall asleep upon the operating table and awaken to find their broken bones set or ruptured organs in place cannot realize the agony of their forefathers who were conscious of every move of the surgeon's hand." Dr. James Gregory Mumford's narration of his own sufferings while undergoing an amputation was related as one of the horrors of a past age.

I wish to call attention to the fact which has been impressed upon me in various ways that a good deal of unnecessary suffering has been inflicted upon the modern surgical patient, even within the twentieth century. I am thankful to state, however, that my record of the following case bears a date in May, 1901: and perhaps the more general availability of nitrous oxide anesthesia and other advantages in recent years has closed the record of similar cases.



Yesterday afternoon, May —, 1901, about 3 P. M. I had occasion to call upon Dr. X. in one of the surgical rooms of the dispensary of a certain hospital in one of our largest American cities. Dr. X. was about to operate upon a bad case of septic cellulitis of the hand, the patient being a man apparently about forty years old. He stated that incisions had previously been made in the hand by some one out of town. Dr. X. injected subcutaneously in several places a solution of cocaine. The solution was apparently injected only very superficially, in fact into the deep layer of the skin rather than into the deeper connective tissue, at about eight points (indicated by the dots) on the dorsal surface of the hand.

Deep incisions were then made in about the situation indicated by the dotted lines . . . . . The middle incision C—D liberated a large amount of thick pus (probably at least an ounce). The incisions A—B and E—F were each probably 1½ inches in length. They were made after the incision C—D. When these three incisions had been made, Dr. X. introduced the handle of his scalpel into the incision A—B, underneath the intervening flaps and apparently close to the dorsal surface of the metacarpal bone of the second finger, bringing the said handle out of the wound E—F, thus making a free opening for thorough drainage between the incisions A—B and E—F.

During the two or three minutes in which the above procedures were being performed the patient gave evidence of great agony; he strained every muscle in an attempt to prevent outcry; he became red in the face with the supreme effort to endure the pain and cried out (as nearly as I remember, and I think I quote exactly) "My God, Doctor, are you near done?" But the worst was yet to come. Dr. X. thrust the handle of the scalpel deep into the middle wound; then withdrawing it he introduced the closed blades of a pair of rather large scissors into the same wound. The man was now thrown into a complete convulsion; he stiffened out upon the chair, or stool, upon which he was sitting; his head descended and his feet arose from the floor so that his rigid body balanced across the seat; his respiration was snorting and for a few seconds he was evidently unconscious in a convulsion. The nurse and an assistant steadied him to prevent him from falling to the floor and Dr. X. quickly turned the hand partly over and causing the end of the scissors in the dorsal wound to project toward the palm as a guide, made a counter-opening in the palm by cutting down upon the end of the scissors with a scalpel, thrust the scissor blades about an inch through the opening and stretched the opening by separating the blades three or four times. This was just completed as the man gave evidence of returning consciousness by sitting more erect, letting his feet drop to the floor, and asking (again in dread or agony) "Oh, Doctor, are you done, are you done?"

Why should not a general anesthetic have been given for this extensive operation on an infected, inflamed "pus-hand"?

About half an hour later Dr. B. and myself witnessed Dr. X. in the act of disarticulating the distal phalanx of the left index finger of another man, in which case also the patient gave evidence of great suffering. Dr. X. said he did not think he was hurting him much, but Dr. B. remarked that "we had better ask the patient."

The foregoing history was written within twenty-four hours after witnessing the occurrences.

Referring to the relief of pain, I once saw a patient suffering with dysmenorrhea who required artificial respiration for more than two hours to save her life, after two 12-grain powders of antipyrine, self-administered, followed by two hypodermic injections of morphine, each ¼ grain, two hours apart, given by physicians on account of her apparently unabated paroxysms of agony. This case illustrates the need of better judgment in the relief of pain. It is only fair to state that the physicians were misled by the statement of the patient that morphine had been administered to her in full doses on previous occasions.

Not to weary you further with the history of an obstetrical case, to complete the consideration of the three divisions of practice, medical, surgical and obstetrical, in all of which our means of relief are inadequate, I will simply remind you of my statement in an earlier part of this paper, referring to the case of puerperal septicemia, that "the patient suffered terribly with all labor pains until relieved by chloroform, and also with after-pains."

The three cases thus related were all unusual; they were all cases of extreme suffering. There are doubtless many cases of minor surgery and obstetrics, as well as painful ailments, for which present

methods of treatment are fairly or entirely satisfactory. But for severer cases of suffering, always bearing in mind the importance of "safety first" and the baneful immediate or later results of some of our remedies, we are bound to acknowledge the need of better facilities for the avoidance and relief of pain.

Crile's anoci-association method of anesthesia does not fall strictly within the scope of the discussion of this paper, since its purpose is to avoid shock rather than pain in cases where pain would be fully relieved or avoided under the measures for which the anoci-association is a substitute.

The morphine-scopolamine anesthesia of Krönig and Gauss, popularly known as "twilight sleep," in obstetrics, on the other hand, comes definitely within our field of consideration. The latter was presented before the New York Obstetrical Society in an exhaustive paper by Dr. W. H. W. Knipe, October 13, 1914 (to be published in the *American Journal of Obstetrics*). The paper was somewhat fully discussed. Dr. Cragin summed up the situation from his own standpoint and experience by saying that the method has its disadvantages as well as its advantages, and that he is not yet prepared to employ it in private practice.

The equipment of dispensaries with apparatus for the administration of nitrous oxide, or gas-oxygen anesthesia, is a very important improvement. We should demand and employ the best facilities now available. Let us cherish the hope that the future will furnish better and better facilities; for, as Milton said, "Pain is the worst of evils, and excessive, overturns all patience."

My purpose here, as you perceive, has been not to exphasize the truly wonderful accomplishments of recent years, but to demand their employment where safety permits, and to express the hope that, as we grow in knowledge and experience, better judgment and better remedies shall enable us to render better and better service to suffering humanity.

19 Fifth Avenue.

THE PSYCHOLOGY OF THE TUBERCULOUS.

By SOLOMON BAUCH, M.D.,

BEDFORD HILLS, N. Y.

PHYSICIAN TO THE BEDFORD SANITARIUM.

Whenever in the history of medicine the conditions of man create a new malady which is misunderstood or the cause of which is unknown, and its ravaging effects unconquered by the scientific intellectuals, these in turn coin words or phrases which tend to cover their ignorance. We are taught to use such words as malaise, discrasia, hysteria, etc., and we usually resort to the phrase "psychic traits" as our savior whenever we are confronted with an obscure symptom complex.

In this paper the writer wishes to discuss the question, whether the "psychic traits" complicating tuberculosis as mentioned by various writers on the subject are peculiar to the tuberculous, or whether we can detect similar psychic phenomena in patients afflicted with other infectious and organic diseases. It is also necessary to ascertain whether it is the toxicity in the blood of the tuberculous generated by the tubercle bacilli which produces in the patient such "psychic traits" as alluded to, or whether we can find other causes which are prior to the patient's contraction of the disease and which would account for such psychic peculiarities.

In a year's experience at the Bedford Sanitarium, the writer has obsesrved that it is as difficult to form a type of the tuberculous as it is hard to pronounce the people in the "melting pot" as being of one species or rank. Each individual in the sanitarium is a type, a mind, and a character unto himself. These people bring with them the stigmata of their past education and environment, and their hereditary influence, also their present knowledge, intellect, and temperament.

The circumstances surrounding a person afford sometimes a greater "vis a tergo" than his own reason. When one is a tuberculosis specialist all the complications and affections in a tuberculous subject seem to him to originate from, and usually to have a direct relation to consumption. Such a narrow view is equally held by the syphilographer, the surgeon, and the internist.

There is no greater mistake in medicine than for a specialist to dissociate his so-called specialty from the other branches of medicine. It is as great a fault to associate any complication arising during the course of a disease or one overlooked by the examiner with one's speciaity without entering in a thorough manner into the causes and effects.

Many writers who wrote on the relation of the "psychic traits" of the tuberculous patient to tuberculosis would attach invaluable significance to one sort of traits, others to another sort of psychic peculiarities. One writer thinks that extreme egotism is a predominant trait in the tuberculous, not as a complication, however, but more as a result of the effect which the toxins circulating in the blood produce.

The same writer does not fail to mention that the tuberculous patient might present other traits such as optimism, mental brilliancy, a feeling of euphoria, and a belief in euthanasia, but never letting loose from his strong hold on the theory that the toxins are the only and sole factor in creating such traits. Other writers have found that the tuberculous patient is abnormal, that some of these patients border on insanity, that other patients show manifestations either of depressive dementia, or hypochondria, of paronoia, or of extreme pessimism. The writer wishes to remark here and now that whatever seems inexplicable in the science of etiology of certain pathological conditions, these poor, misguided, phantasmagorical toxins are always blamed.

To deny the fact that "psychic traits" are found in the tuberculous is to deny the truth of the Newtonian law of gravitation or the Copernican system. To attach so much importance to the tuberculous toxins as a cause of these "psychic traits" means that the writer must deny himself the privilege of claiming to possess a mind which has the capacity to observe, reflect, reason and think.

A few examples of patients who were observed by the writer at the Bedford Sanitarium will prove to the reader the soundness and accuracy of his claims.

Mrs. K. was of a very irritable nature. She was one of those people whose exactness of purpose and action stimulated in her an extreme nervousness and a quick temper. She was always dissatisfied and discontented with her lot. She simulated more a dyspeptic than a tuberculous patient. Her anamnesis tells us that she was that way a good many years prior to her contracting consumption. In her case it is more likely that such a disposition would render a person susceptible to phthisis pulmonalis rather than that the converse of it be true. She had, though, one virtue, which overbalanced her many vices. She possessed intelligence. The patient died a few months ago. A striking exam-

ple of control this patient showed a few days or weeks before her demise, when in agonies of pain she would always control her complaints in the presence of her young daughter who would visit her frequently, and this alone overthrows the idea of tuberculous toxins producing the sense of egotism. This woman, in whom her sufferings and the severe attacks of coughing might have created a bitter feeling against all humanity, and made her apathetic to the needs of her own children, showed a heroism which cannot be surpassed. She utilized the two great factors of her intelligence —courage and love. To spare her children she would not utter a groan, and her conversation would turn to any subject other than the one most pressing, namely her malady. As soon as these beloved ones would leave the bed, just so soon could be noticed a metamorphosis in her appearance and attitude toward the bystanders. She no longer tried to conceal the evidence of excruciating pain, severe dyspnea, and extreme dysphoria.

Mr. G., a man about forty, of good character and sedentary nature. Prior to contracting tuberculosis he was a very loyal and faithful husband and father. He toiled for twenty years without a single holiday. He possessed two vices, smoking cigarettes to excess and indulging moderately in alcoholic beverages. To counteract these vices, he possessed a keen intellect and splendid acumen. No sooner did he discover that he was a victim of this plague, than he began to read about it and having found out its tendency to chronicity or fatality, he changed by virtue of his reasoning. He became the real egoist, neglecting his family and being indifferent to their needs. He became an inebriate, smoked the more, and died a speedy death. His reason for this sudden change was that he was grasping the opportunity to enjoy for once a vacation, since there was no hope that he might survive his trouble. Regarding the treatment of his family he claimed they could live long after he was gone and in time even forget that he ever existed at all.

Mr. S., a young man, a recent graduate of a college, is sagacious, ambitious, and efficient. He is very conscientious in whatever he undertakes to do, and probably as a result of this, he contracted tuberculosis and he is now doing very badly. He is in the third stage of the disease, extremely dyspneic on the slightest exertion, very cyanotic, anemic, and emaciated, but he expresses a sense of euphoria whenever the question about his health is put. He claims he is in need of activity and that nothing is seemingly too difficult for him to do when forsooth the best thing he can do now is to lie absolutely relaxed in a supine posture. What is in his mind is hard to discern. He is not a fool in matters other than that touching his trouble, but he is almost bordering on paranoia when his disease is the subject of discussion. This mental attitude could be explained only by the fact that his brain is of much sounder health than his soma. It is the struggle between the ego and the me—between the subjective personality and the objective being. It is the strife between his cellular potentiality endeavoring to assert itself and the disease combating it. He does not fight for life's prolongation, but for what life would convey to him and to his world should he be able to give it expression.

Miss K., a young woman who is of a reticent, sedate, and passive nature. Her mental as well as her physical resistance is below par. She is now in the domain of phthisis florida. Her nature plus the disease has robbed her of the "will to live" and she is consequently an extreme pessimist bordering on melancholia and probably, if her condition be prolonged, on depressive dementia.

Mr. C., a married man whose material circumstances caused his family to live on charity. He has a moderately advanced tuberculous lesion and seems to be aware of the fact. This man is of a garrulous and sprightly nature. Life to him simulates happiness. He has no past and no future, the only time worth while to him is the present. This present according to his views has to be utilized to the best of his advantage and it is not worth while being disturbed by no matter what misfortune may befall him. He is an epicure incarnate. Disease, poverty, degradation, and humiliation are not found in his vocabulary.

All the examples mentioned above are a select group of individuals who help us see the psychic traits in their full bloom and their "raison d'être." In tuberculosis, as in other diseases, each patient is an individual unto himself. The psychic traits of these individuals may stand out more prominently in the tuberculous than in any other chronic disease, but the reason is self-evident; consumption is more common, its effects are more easily felt, and its ravages more known to the laity than those of other diseases.

The fatality of the disease and the ease with which the knowledge of such sad fact is spread renders the victim more susceptible to suggestion of any sort because the "urge to live" is more or less implanted in every one of us.

Then to judge hastily and classify the tuberculous as abnormal, as one writer has done, is to brand the victim of phthisis pulmonalis with a cruel and heartless epithet. They are not abnormal but sick, and they need the help of the physician to lessen the effects of any threatening phychic trait which is undesirable and dangerous to the patient's health.

The attention paid to the tuberculous patient and the confidence exacted from him go a long way in alleviating the sufferer. We can not, therefore, put the tuberculous in a particular mental category, but it remains for us to study each one's nature and direct our therapy in accord with his nature.

CATATONIC STATES IN MANIC DEPRESSIVE INSANITY.*

By JOSEPH SMITH, M.D.,

BROOKLYN, NEW YORK.

SENIOR ASSISTANT PHYSICIAN TO THE LONG ISLAND STATE HOSPITAL.

In 1874 Kahlbaum described as a disease entity a condition which he named catatonia and which presented the following group of symptoms: stupor, mutism, negativism, stereotypy, mannerisms, impulsive actions, automatic obedience, and muscular rigidity or flaccidity. The disease occurs in the young and terminates in dementia. Later, Kraepelin, taking into consideration the final outcome of these conditions, included the cases showing a few or all of these symptoms into his great group of dementia praecox. Experience, however, has shown that catatonic symptoms may appear in cases which do not deteriorate. They may also occur in the symptomatology of senile psychosis, involution melancholia, and epileptic psychosis. Thus we were forced to the conclusion that catatonic symptoms per se do not justify diagnosis of dementia praecox. The greatest difficulty, as far as differentiation is concerned, is presented where this symptom complex appears in, or dominates the course of, a manic depressive psychosis. Hence, it is unsafe in the presence of this symptom to prognosticate. Of greater moment is the *character of the onset* of the psychosis and the *soil* on which it is engrafted. Given an individual of a generally lively disposition, an active, energetic and "open" personality, a rapid onset of the catatonic symptoms, and you may safely prognosticate a good outcome. When, on the contrary, the disease appears to develop rather slowly in a person with "shut in" tendencies, you may suspect a deterioration process. Kraepelin, who devoted a great deal of space to the differentiation between catatonic stupor and manic stupor, had to recede from his former position, inasmuch as a wider knowledge had convinced him that a good many cases he formerly classed as dementia praecox belong to the manic-depressive group. Certain

*Read at a meeting of the Brooklyn Neurological Society, December 2, 1914.

phases, however, of catatonia such as mannerisms, stereotypy, echolalia, and echopraxia are distinctly dementia praecox reactions. Now, I wish briefly to review a case in our service which will illustrate my preliminary remarks:

M. K., admitted November 19, 1910. Family history.—Mother is suffering from manic-depressive insanity. Personal History.—Patient was born in Austria in 1894. He was 16 years of age at the time of admission. He is the oldest of a family of seven children. He came to the United States four years ago, and attended public school until a year and a half ago. The patient developed normally, was bright and active. Onset of Psychosis.—Five days before admission he returned home from work feeling nervous. He stated Hospital, whither he was sent for observation, he answer questions; asked his sister to administer poison to him; thought he was followed by detectives; cried; took little nourishment; slept poorly. He said: "Let us (meaning the whole family) kill ourselves, then we won't have any more trouble." At the Kings County Hospital where he was sent for observation, he answered questions slowly, complained that people on the street and in cars looked at him in a peculiar manner, children throw stones at him; he felt sad and worried, and wanted to die. He refused food because he thought it would collect in his stomach, and it may eventually kill him. He thought the examiners were detectives. When admitted to the Long Island State Hospital his memory and orientation were intact. He expressed the idea that his sisters and his father's business partner put poison in his food. He said his heart and his head were affected. He sat about the ward taking no notice of what occurred about him. He said: "I will tell you the truth; I don't know what my name is. I told you what it was, but I was told by good people that I did not know what I was talking about." Some of his replies were silly. He was afraid that mice, cats, and cows would kill him because he did not feed those animals while in the country. He felt despondent because he did not act on his father's advice not to eat sweet potatoes, etc. He was going to be harmed here because he harmed others. In December there was some improvement noticeable, though he was retarded in his speech, and he complained of a general weakness and some difficulty in thinking. In January he became again depressed. He was very quiet, and very little information could be obtained from him. He said he worried about being in a strange place, that he was afraid. In February he became mute, negativistic; had to be put to bed and tube fed. There was no change observed in March. He was still mute, would hold saliva in his mouth, would stand for hours in the same place on the ward. At times he would refuse food entirely, on other occasions he would eat only stale bread. In April he had an attack of facial erysipelas, from which he made a good recovery, and early in May he was still catatonic but took food voluntarily. Improvement began in June. In July he became somewhat elated, mischievous, interfered with other patients. This condition, however, was of a transient nature, and he was discharged in September as fully recovered. He remained well, and was steadily employed up till April 20, 1913, when he began to complain of not feeling well, went to bed, and remained in it for nearly two days. Then he became talkative; said he would make lots of money and would support the whole family; he was restless at night, became aggressive, struck his sisters, and his commitment followed. On admission, he was loquacious and elated, gave utterance to grandiose ideas. He told the examiner he was worth $2,000, and that he could make a million dollars out of the newsstand he had. His memory and orientation were excellent. In his spontaneous utterances he exhibited flight of ideas and some distractability. He was quick to respond to direct questioning, but his answers were replete with unnecessary detail. He performed multiplication tests quickly and correctly. His attention could easily be obtained. He had a subjective feeling that he was nervous. For a few days after admission he was confined to bed, but he was restless, interfering, and voluble. Early in May he became mute; would hold saliva in his mouth; he was dull and listless. His muscles were flaccid. He offered no resistance; there was no negativism shown, but he would stand idly about in one position, or sit in a chair with his head bent for hours; refused food, and was tube fed. A few weeks after this he became talkative one morning, but when the physician approached him he again became mute. At times he would eat his meals heartily; then again he would refuse all food. He remained in bed inaccessible until late in June when he began to converse, but his answers were given in a slow manner. Since that time, however, patient has been steadily improving. He showed a surprisingly good memory for events that occurred since his admission to this institution. Interest in surroundings slowly returned, and at the time of his parole, Oct. 18, 1914, he had recovered completely. He showed good insight; explained his delusions on a rational basis. At the present time he is working at Rockaway, Long Island.

Summary.—We have here a recurrent psychosis in a young individual. The first attack was initiated by depression, the second by exaltation. In each attack the most striking features during the course of the disease were the catatonic phenomena, almost alike in both attacks. Recovery followed each attack, and there is not the slightest evidence of any deterioration in him. There cannot be any doubt as to the diagnosis of this condition—manic-depressive insanity—the recurrence of the attacks, the depressive and exalted phases, the termination in complete recovery are decisive. What I wish to emphasize here are the catatonic features which have for a time obscured the manic-depressive picture. The greater lability of mood, the rapid onset, the "open" personality, the mild manic features in the second attack, and the depressed mood in the first are the real criteria for diagnosis. The delusions of the patient play an insubordinate role in the psychosis. He who would not be accused of rash diagnosis should take cognizance of all the symptoms in a given case, and pay particular attention to those features which I have here discussed and emphasized.

SOME PECULIAR MOULD DISEASES.

By B. G. R. WILLIAMS, M.D.,

PARIS, ILL.

In the routine of diagnostic laboratory work, moulds have usually been considered extraneous and without pathological significance. While every mould found in these specimens cannot be considered worthy of note, now and then it happens that they appear in large numbers even in fresh specimens, that other parasites are absent, and that recovery or relief from symptoms follows their disappearance.

Some moulds, as those of certain skin diseases, have been classified as parasitic for man; but in the case of others biological exaltation has been overlooked, it being inferred that, if they have any significance, they are merely secondary invaders, such foothold being made possible by virtue of the presence of true pathogenic percursors. Or a more frequent explanation is that for various constitutional reasons (often assumed to exist) the body resistance has been lowered and that semiparasitic fungi are thus permitted a foothold. In either case it is usually agreed that any foothold gained by moulds (save the few distinctly pathogenic ones) is very insecure, and that if possible to reach them by proper treatment they are easily dislodged. The frequency of spores makes recurrences the rule.

Identification.—Because of the fact that non-pathogenic moulds are likely to grow in laboratory specimens, the examination of freshly secured material is imperative. Where the specimen is dry and probably contains tissue, the preparation may best be made by removing a portion of it to a glass

slide and adding a drop or so of liquor potassæ. Place a cover glass on it and allow it to stand for five minutes. Then press down the cover glass, and examine with low power, narrowing the iris diaphragm somewhat. This will demonstrate very nicely both the mycelium and the spores.

Smears may often be made where the material is not crustaceous, and may be stained by Loeffler's methylene blue. In the smearing the mycelium will usually be broken up into irregular and often branching or budding sticks. Spores take the dye easily, in fact, stain much more deeply than the body cells, and being elliptical in appearance are easily identified.

Cultures are easily obtained on all media, and especially well upon glucose agar. As a rule stained specimens are not quite satisfactory as permanent mounts because of the alterations which occur during desiccation. It is better to mount unstained preparations in glycerin and add a cover glass, making permanent by a ring of asphalt around the edge of the latter.

Bronchial and Pulmonary Moulds.—I shall pass without comment the various pathogenic skin moulds, as they are more or less familiar to the majority of clinicians, and give attention to some of those not so well understood. I have mentioned above that all specimens must be examined when fresh, and this holds especially in the case of urines and sputa. In fact, moulds may be found even in fresh sputa and be regarded as nothing more than extraneous (from oral cavity and so on). But now and then a chronic bronchial or pulmonary disease may be characterized by the finding of moulds in large numbers and by the absence of pathogenic bacteria. Moreover, when the sputum is rid of these moulds, the recovery is often prompt; there is relief even when tuberculosis is the foundation. Many mould diseases of the respiratory passages have found their way into the literature; and I have one case of simple mould disease to report, where the symptoms were those of pulmonary tuberculosis. And yet a course of iodide caused a disappearance of both moulds and symptoms.

In Pregnant Women.—I have been intensely interested in the rôle of certain of the thread fungi in the vaginal and vulval irritations of pregnancy. This has been overlooked or ignored by most of our obstetricians. Inquiry among his clientele will quickly prove to any physician that a large percentage of pregnant women are affected to a greater or lesser extent. In the severe forms, the woman complains of a "burning leucorrhea." The discharge is serous, but contains white or gray masses. The labia and inner surfaces of the thighs become scalded and often show the usual signs of simple inflammation. It is not a true eczema of the vulva, for it is easily remedied by attention to this discharge. The reaction of this is highly acid, and the masses when examined prove to be mycelia. The use of cleansing douches may give relief, but spores will be found even during these periods. The local symptoms may subside, but suddenly comes the discharge again with a recurrence of the suffering. Many of our patients suffer from this trouble to such an extent that the next pregnancy is dreaded. It is of sufficient importance to demand a more thorough study by those of us who scorn the minor things of obstetrical practice, apprehending only placenta previa, eclampsia, and contracted pelvis. The question of rational treatment here, as in thrush and all mould diseases, is one which the obstetrician must solve. Much has been said concerning the use of acid versus alkaline washes. As a matter of fact, moulds grow equally well in alkaline and in acid media, so neither can do much to inhibit their proliferation. But for the simple reason that in their growth they form acids, it is well to use alkaline washes to neutralize these. Formalin quickly destroys moulds, and may thus be used in the oral cavity. In the vagina of the pregnant woman, however, we hesitate, since we do not wish to slay the Doederlein bacilli whose mission it is to protect against the pyococci of puerperal infection. Unfortunately the good effects of iodides noted in mould disease elsewhere, cannot be obtained here. The condition is important, and demands careful study.

Stomatitis.—Thrush is usually meant when speaking of mould stomatitis, but I have seen one case where the patient was past the age of thirty and the clinical manifestations as well as the laboratory examinations were not those of thrush. The lesions were located on the soft palate and the pillars, and appeared as very large grayish-white patches or masses which, when rubbed loose, were followed by bleeding. In other words, the clinical picture, while not exactly that of diphtheria, was confusing. The microscope revealed blood, epithelial cells, spores, and mycelium. The growth was much coarser than that of the *Oidium albicans*. Recovery was prompt after the use of the formalin gargles.

Conclusions.—These cases, as well as others which have been reported, are of sufficient importance to direct the attention of the physician to the frequency of pathogenic mould diseases of the mouth, bronchi, lungs, and vagina, the diagnosis of which may be established by proper diagnostic and therapeutic tests.

A TUBE FOR USE IN PHLEBOTOMY.

By WILLIAM SPIELBERG, M.D.,

NEW YORK.

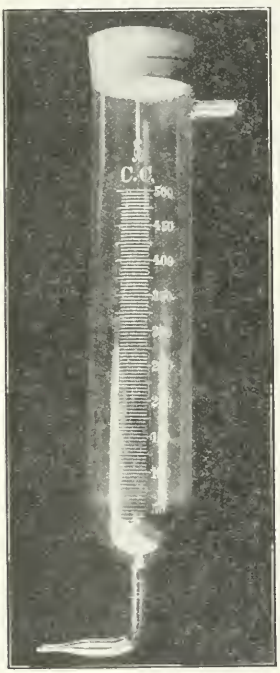
HOUSE PHYSICIAN, BETH ISRAEL HOSPITAL.

In performing venesection a number of difficulties and disadvantages are encountered. They are: (1) In accurately measuring the amount of blood removed. (2) The length of time necessary for the operation. (3) The unpleasant effect of the operatin and the bystanders, whether relatives or nurses, and on the patient, who frequently attributes immediate or subsequent symptoms that may develop to an excessive loss of blood. (4) In keeping bed clothes, assistants, etc., from getting soiled with blood. (5) The formation of blood clots either at the opening in the vein or in the cannula if latter is used. In this communication I desire to describe a new tube for performing phlebotomy which will overcome these difficulties. First, I fitted a tube used for salvarsan injections with a medicine dropper, holding the two together by a small piece of rubber tubing. This arrangement worked well, except that after obtaining about 300 c.c. of blood, the latter would often not ascend rapidly enough, due to the formation of a clot at the junction of medicine dropper, glass cylinder, and rubber connecting tubing. To overcome this defect I devised an all-glass tube shown in the illustration.

A cylindrical tube of a diameter of about 2 inches is graduated into ten cubic centimeter divisions. The capacity of the tube is 500 c.c. The lower end of the apparatus is drawn out into a tube of a diameter

of about one quarter of an inch, which is bent at right angles about one inch from the bottom of the cylinder. The end of this narrow tube is drawn out to a point about 1/16 of an inch in diameter. About one inch from the upper end of the vessel (into which fits a rubber stopper) is an outlet one inch long and ¼ inch in diameter. The purpose of this outlet is two-fold: (1) To provide for suction if necessary, to facilitate the blood flow. (2) To prevent leakage of blood when the apparatus is removed from the vein, by holding the thumb over the opening of the outlet.

With a turniquet applied to the forearm, the vein selected is usually the medium basilic, although any other vein below the bend of the eblow will serve the purpose. The incision is both transverse and vertical, although the latter through a one-inch incision is the better one, as it exposes more of the vein than



Tube for use in phlebotomy.

the transverse incision. Both can, however, be used with advantage. After exposing the vein for about one inch the proximal and distal ends are clamped with bulldog clamps, thus isolating the vein, which dilated with blood stands out prominently. A slit is made near the proximal clamp and the tip of the phlebotomy tube is inserted towards the distal clamp as far as it could go. The distal clamp is then removed and tip of tube inserted further. This is immediately followed by a rush of blood into the tube, which fills up to the 500 c.c. mark in less than 4 minutes. When a sufficient quantity of blood has been obtained the turniquet is removed and the tip of tube slowly withdrawn. It is of interest to observe in some cases with a rather low blood pressure how rapidly the column of blood rises in the cylinder in spite of the pressure it has to overcome in doing so. We found it unnecessary in any of our cases to produce a vacuum in order to obtain the desired quantity of blood. We have removed in almost every instance between 400 and 500 c.c. or more.

The following are the advantages claimed for the above method and tube:

1. Accurate measurement of quantity of blood removed.

2. Time saved in withdrawing the blood, taking 4 minutes at a maximum to withdraw 500 c.c. of blood.

3. Neatness and cleanliness of operation.

4. No assistance is required and the method is therefore applicable in private practice.

5. Its good effect on the patient, nurses and bystanders as compared with other methods used.

In looking through the literature I have failed to find a similar tube to the one I describe.

Medicolegal Notes.

Evidence as to Patient's Treatment and Condition.—There are questions requiring scientific or expert knowledge which can only be answered by those possessing the requisite skill and knowledge to give their answers probative value, and persons not so qualified are therefore not competent witnesses as to questions depending wholly on such scientific or expert knowledge. Whether the treatment of any particular injury or case was proper, or whether a surgical operation was skilfully performed, or whether a particular disease resulted from alleged negligent treatment, and like questions of science, must of necessity depend upon the testimony of physicians and surgeons learned in such matters, but such questions are not identical with the ultimate issue to be decided by the jury.

The foregoing rule does not have the effect of limiting or proscribing the testimony of non-expert witnesses as to particular facts within their knowledge which may bear upon questions depending for their ultimate solution upon scientific knowledge. In a malpractice suit, facts relating to the treatment and the condition of the patient may be stated by such witnesses, though they may be incompetent to give an opinion as to the value or effect of such facts from a medical or surgical point of view.—Longfellow v. Vernon, Indiana Appellate Court, 106 N. E. 178.

Barking Dog Held Nuisance to Practicing Physician.—A physician residing and practicing in Pittsburgh, Pa., who made a specialty of practice of the eye and ear, asked for an injunction against neighbors to restrain the keeping of a dog on their premises on the ground that it was a disturbance to the plaintiff and his family and interfered with his practice as a physician. The defendants were husband and wife, and as sub-tenants occupied a portion of a house the rear of which was located about twenty-five feet from the rear windows of the room of the plaintiff's house occupied by him as an office. For several months the defendants had kept a dog in their premises which for one or two hours nearly every day while the defendants were absent barked and yelped to such an extent as to annoy the plaintiff and his wife. and particularly when he was making a physical examination of a patient the disturbance caused by the dog was sufficient to interfere with making a satisfactory examination. An injunction was granted solely on the ground that this was a nuisance to the plaintiff in his professional work.—Hechelman v. Kindt, 40 Pennsylvania County Court, 277.

Effect of Waiver of Privileged Communications in Insurance Contract.—The rule as to privileged communications between a physician and patient is for the benefit of the patient and not the physician, and the physician is not entitled to claim the privilege where the patient has waived it. A member of a benefit society waived privileged communications between himself and his physician in his contract. It was held in a suit against the society for the insurance that the action of the court in allowing the physician, who was called as a witness for the defendant, to refuse to testify on the ground of privilege was reversible error.—Cronin vs. Court of Honor, 187 Ill. App. 480.

NATURAL AND ARTIFICIAL IMMUNITY IN DIPHTHERIA.

THERE is probably no other disease than diphtheria in which theory and practice are so closely interwoven, in which laboratory and clinic are so intimately associated, and in which research is so markedly stimulated by bedside experience. For this reason, and also because it represents the pioneer achievement of modern scientific medicine in the battle with infective disease, diphtheria possesses a perennial interest. Although many of its problems have been solved, there are a great many more that are still veiled in obscurity. To-day the focus of investigation in this disease is the question of natural and artificial immunity.

Within recent years there have been published the results of many studies in this domain, studies concerned with the methods of determining the degree of natural immunity in any individual case, with the influence of diphtheritic infection upon the preexisting natural immunity, with the mutual influence of passive and natural immunity, with the production of active immunity, and with the ready clinical determination of the presence or absence of natural immunity. Without discussing in detail any of these problems with which most medical readers are already familiar, it may be of interest to point out a few of their most striking characteristics. A very comprehensive survey of this field has been contributed by Hans Kleinschmidt to a recent issue of the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung* (Vol. 3, No. 3).

Of eminent significance is the fact that 93 per cent. of newborn infants have an antitoxin in their blood no different from that which is artificially formed in animals, or which develops in human beings after these are infected with the diphtheria bacillus. This natural immunity of young infants rapidly diminishes during the first year of life, and later, up to the fifth year, so that of infants one year old 57 per cent. are immune, and of children from 2 to 5 years of age 37 per cent. are immune. From this age onward to the fifteenth year 50 per cent. of the individuals are naturally protected against diphtheria. This proportion increases to 76.6 per cent., between the ages of twenty-one and forty years, and then diminishes to 48.2 per cent. up to the sixty-fifth year. The above figures correspond very closely with clinical experience as to the age incidence of diphtheria, namely, the rarity of this disease among infants under six months of age and the relative rarity among adults. It has been shown that the natural immunity of the mother is transmitted to the child *in utero*, and that even the nursing infant receives antitoxin in the milk. The increasing immunity in later childhood and in adult life is to be attributed to a latent infection, which fact corresponds very closely with one's knowledge as to the prevalence of diphtheria carriers.

The above data can now be easily verified with the aid of the so-called Schick test, in which, as the result of the intracutaneous injection of a minute quantity of diphtheria toxin there develops at the end of from twenty-four to thirty-six hours a circumscribed area of redness and infiltration, persisting for from seven to ten days, and fading with a superficial scaling and a persistent brownish pigmentation. This reaction which is the result of the irritant effect of the diphtheria toxin, occurs if there is less than 1/30 of a unit of antitoxin in one cubic centimeter of the blood of the individual tested; in other words, it indicates the absence of immunity. A negative reaction shows that the individual has a sufficient amount of antitoxin in his blood to protect him from infection with the Klebs-Löffler bacillus.

Within certain limitations the practical value of the Schick test is perceived in a number of directions. In doubtful cases of diphtheria in which bacteriological examination is not conclusive, a negative Schick reaction, indicating the presence of antitoxin in the blood, would speak against the diagnosis of diphtheria, at any rate if the illness has lasted only a few days. As a means of enabling one to make a retrospective diagnosis of diphtheria in cases of paralysis, etc., in which there is no definite knowledge of a preexistent diphtheria, the demonstration of an absence of antitoxin from the blood about three or four weeks after an illness would indicate, although not absolutely, that this was not diphtheria. Another important application of the Schick test consists in determining among those who have been exposed to diphtheria which ones are and which ones are not immune, so that prophylactic inoculations of antitoxin may be made in the latter instances only. This measure would mean a real economy in public health administration and would tend to restrict the possibility of serum sickness.

The active immunization of individuals by means of inoculations with diphtheria vaccines although a method promising much for the future, is not as yet adapted to general use. Behring's toxin-antitoxin mixture, the exact composition of which is still withheld from the profession, when injected into an individual, sets up an immunity at the end of ten to fourteen days, a period so long as to render this method by itself of little value in the case of individuals who have been exposed to diphtheria and whom one may desire to protect. This disadvantage may be obviated, Kleinschmidt says, by the simultaneous use of passive and active immunization.

THE NERVOUS SYSTEM IN NAVAL WARFARE.

War as it is now waged on sea or land obviously must place a great strain upon the nervous system. The most modern weapons of destruction, including immense guns, explosive shells, aerial arrows, and the various types of flying machines, have rendered war more trying by far to the nerves of the combatants than was formerly the case. But if fighting on land is more nerve racking than of yore, battles on the sea are yet better calculated to shatter the nerves of the participants. The tension produced by waiting for and dreading an attack, in these days of submarines and airships, cannot but tend to bring about certain mental affections in some. In the United States *Naval Medical Bulletin* of October, 1914, is a paper which first appeared anonymously in the *Marine-Rundschau* XXI No. 5, translated into French by Marcaudier for the *Archives de Médecine et de Pharmacie Navales*, April, 1914, and translated into English by Dr. I. W. Richards, Surgeon U. S. N.

Among other statements made in this paper is the following: "Reports based on figures from the last great wars show that the number of mental diseases is greater for all combatants, but in particular for the officers. The number of cases increases a little after the outbreak of war, reaches a maximum when the war attains its full development, and does not fall again until long after it has ended. For the Russian army during the last war the figures rose to 2 per 1000. For the army in the field one notes especially cases of excitement and mental confusion. Individuals placed in a state of lowered resistance by alcoholism, former illness, or hereditary traits were the first to be attacked. If, as has been said, an increase in the number of these cases is a fact signalizing every war, this proves that among all the men assembled many carry the seeds of an affection perhaps already recognizable by an alienist; others have had nervous trouble during their youth which will become aggravated under the influence of fatigue until manifested by symptoms which can no longer be overlooked. Mental maladies are becoming better and better known, and if the number of cases cited in reports is increasing, this increase may be accepted with satisfaction as a sign that we understand more clearly how to search for and recognize these affections."

The paper is summarized thus. The primary requisite for the success of a fleet in a naval war is a healthy personnel, so far as the nervous system is concerned. All possible measures should be taken, therefore, in the fleet to overcome the damage caused by inviduals defective in this respect, in view of grave developments and to assure the selection of men in the best condition. If it appears that in recent years there has been a slight increase in diseases of the nervous system this fact need not cause any anxiety regarding sanitary conditions. On an average the crews are in a condition to meet every exigency. Medical officers must eliminate the weaklings from the navy and see that they are replaced as far as possible by an equal number of sound men. There is no peril in the present situation. Diseases of the nervous system are only a menace to an exhausted people who cannot make good their deficits.

The moral to be drawn from this valuable paper would seem to be that the examination of the would-be naval fighters should be of an especially searching character. In particular, should those who exhibit symptoms of an unstable nervous system be subjected to severe tests. For this purpose, the services of alienists would have to be called in, but when the absolute necessity, under modern conditions of naval warfare, for having sailors sound in mind and body is considered, there is little doubt that such a course should be followed. The modern naval seaman must have no physical or mental defects, and the only means of insuring this as far as possible is by a particularly rigid examination.

THE EFFECTS OF HEAT ON DRIED IMMUNE SERA.

It has long been known that if immune sera in their natural condition are subjected to the action of heat, they will lose their effectiveness even if the degree of heat is insufficient to bring about coagulation of their contained albumin. The specific antibodies contained in these sera are, therefore, comparatively thermolabile. It is also known that proteins which coagulate when subjected to a moderate degree of heat while in complete solution will remain unaltered if previously dried, even though the amount of heat be greatly increased. For instance, albumin in watery solution coagulates at about 58°. If now absolutely all the water is removed it must be subjected to a temperature of 170° before it will coagulate. On the basis of these observations Matsuda has been carrying on some experiments on the effect of heat on immune sera which have been dried. He found (*Centralbl. f. Bakt.* 1914, lxxxv, 83) that if he dried cholera immune sera, diphtheria immune sera, or hemolytic sera over calcium chloride at room temperature he was later able to heat the dry residue to 95° for twenty-four hours without reducing the power of the sera to neutralize toxin or to hemolyze red cells. Only after heating to 95° for four days was there any perceptible diminution in the immune bodies.

The observation itself is of interest and is an excellent demonstration of the necessity of the presence of water for all reactions of this sort. Matsuda, however, goes further and offers this method as a means of protecting the serum against infection or of freeing it from non-spore-bearing bacteria which may have found their way into it. It would seem obvious that if the serum were absolutely dried the resistance to heat of any bacteria which it might contain would be increased equally with that of the immune bodies so that the subsequent heating would have but little sterilizing action. The method of drying which he used is not nearly so good as the one of freezing and drying in a vacuum. This latter method takes much less time, since it can be accomplished in a few minutes with the proper apparatus, and it has a

far less injurious action on the antibodies. The preliminary freezing avoids the concentration of the substrate which is bound to take place in any other method. The preservation of sera in the dried state offers many advantages which will some day be acknowledged, but there is great doubt whether the subsequent heating of this dry material can bring about any desired effect.

Gas Phlegmon and Gas Gangrene.

These lesions have been but little known in warfare. In fact only within the past ten years has their nature been fully understood. Naturally crepitation is characteristic of spreading gangrene of the subcutaneous tissues, and this crepitus is due to a certain degree of emphysema resulting from decomposition of the gangrenescent tissues. But in some localities it is possible to show that wherever trauma is possible emphysema could be due to entrance of air from without. True gas gangrene, however, is due solely to the activities of gas-forming bacilli. The latter include nearly all the anaerobic bacteria, so that there should be a definite causal group of lesions, including tetanus, gas bacillus lesions, malignant edema, and others as yet problematical. No one can diagnose a true gas gangrene without cultural tests. If any strain of anaerobes is able to form gas *in vitro*, on culture media, it is presumably an organism which can cause or has caused gas phlegmon or gas gangrene *in vivo*. In addition to the causes of tetanus and simple gas bacillus lesions, there is another anaerobe which inhabits the same earth, which plays a role in the genesis of malignant pustule and malignant edema. In animal experiment it is sometimes difficult to distinguish clinically between these types. The reader will recall that in 1892 E. Fraenkel discovered the gas bacillus which goes by his name. This was easily recognizable throughout the world as the familiar cause of gas gangrene. In military supplement No. 14 of the *Muenchener medizinischer Wochenschrift*, which appears in No. 45 of that periodical, Fraenkel, by request, reports his views on the subject of gas gangrene. This report lays weight on the essentially grave prognosis in this class of cases. Within a few hours this type may involve an entire limb, and patients are beyond the reach of treatment. Once an early diagnosis is made, however, the tissues should be divided right and left and oxygen infiltrated therein by means of a bomb. In addition hydrogen peroxide tampons must be freely used. The author recommends this procedure as all that is at present available under war conditions.

Impounded Water and the Prevalence of Malaria.

Stagnant water in a country in which mosquitos are present is always a menace to the public health. There are in mosquito breeding districts of the country many artificial ponds constructed for industrial purposes. Power plants and railroads, for instance, make ponds and dams. Dr. H. R. Carter writes in the *Public Health Reports* of December 25, 1914, concerning impounded water and the prevalence of malaria, with especial reference to a malarial survey of certain such waters undertaken by the Public Health Service. "The object of the survey is to determine (1) the influence such waters exert on the incidence of malaria, (2) what conditions affect this influence for good or ill, and (3) what measures can be taken to minimize the ill effect of such waters and to increase to the maximum their good effect. The surveys are to be physical and zoological. The first is to determine if the physical conditions of the places examined are such as would make them suitable breeding places for anopheles. The second is to determine what places actually are breeding malaria-bearing mosquitos. There is little doubt that this scheme when carried out will yield a good deal of valuable information and will be productive of a considerable amount of good in hindering the prevalence of malaria. It has been clearly demonstrated that if the steps taken actually prevent the breeding of mosquitos, malaria will be extinguished. The plan, therefore, of the Public Health Service is in the best interests of public health and should meet with the earnest cooperation of power-plant owners, railroad authorities, and all those who are responsible for the construction of ponds in mosquito-infested parts of the country."

News of the Week.

American Red Cross in France.—The French Foreign Office has advised the American Red Cross that the Minister of War, "appreciating the generous and valuable services of American Red Cross units at Pau," is desirous of sending at least one of these units, consisting of three surgeons and twelve nurses, to the north or the east of France, where a large number of badly wounded soldiers are in need. As the two hospital units at Pau have a great deal of serious work in hand, it has been thought best not to remove one of these units from Pau. Offer of an additional American unit of three surgeons and twelve trained nurses has been made for service at Dunkirk or such other place as may be designated by the French Minister of War.

The American Ambulance at Neuilly.—A number of British army surgeons who recently visited the American Ambulance at Neuilly expressed their admiration of the perfect arrangements made for the care of wounded. After an inspection of the wards brief addresses were made by Sir Almroth Wright, Sir Berkeley Moynihan, and Dr. Alexis Carrel.

Drafting Army Surgeons in Italy.—The Italian Government recently ordered the senior medical students throughout Italy to attend a special course in emergency surgery in the field hospital service. They have now been drafted into the medical corps of the army.

Iron Crosses for Nurses.—A dispatch published in *The Sun* says that thirty-eight nurses of the German ambulance corps have been decorated with the Iron Cross by Emperor William and that other women soon will receive the decoration, which hitherto has been given only to men.

Committee of American Physicians for the Relief of the Belgian Profession.—A recent visitor to Belgium says of the desolation there: "No one who has not been to Belgium within the last five months can picture, can even dimly conceive that country's desolation. . . . Wherever our ambulance cars went they met endless processions of refugees: endless, for the straight, flat Flemish roads are endless, and as far as your eye could see the stream of people was unbroken: endless, because the misery of Belgium is endless: the mind cannot grasp it or take it in. . . . It was not flight: it was the vast, unend-

ing movement of a people crushed down by grief and weariness, pushed on by its own weight, by the ceaseless impact of its ruin. . . . I saw six thousand refugees sleeping on straw in the Palais des Fêtes, packed so tight on the floor of the immense hall that there was no standing room betwen any two of them. . . . You could not believe what you saw: you were stunned as if you yourself had been crushed and numbed in the same catastrophe."

An American gentleman who saw the food and clothing put into the hold of the steamship *Lynorta*, which took supplies for the State of Virginia to the Belgians, crossed the Atlantic on the ship and went into Belgium to watch the distribution of the articles among the people. He has returned and declares: First, that every pound of flour and every article of clothing sent from America by the Relief Commission is received by a Belgian; and, second, that all who get such gifts are in direst need of them. Hunger seems to have broken down all class distinctions in Belgium. Captain Green of the steamship *Batiscan*, which sailed with food from Philadelphia on December 6, says that the suffering among the Belgian people cannot be exaggerated. Linden W. Bates, manager of the Commission for Relief in Belgium, states that within a few months the bread lines in Belgium will be 2,500 miles long, which would reach from New York to Salt Lake City.

Physicians and their families have shared the common fate. Appeals for food, drugs, and clothing are numerous and urgent. The resources of this committee have been so limited that it has not felt justified in sending anything but food to our starving colleagues. One hundred and fifty-six physicians and eleven medical societies have thus far contributed to this fund. There are approximately 142,300 physicians in the United States. If each one would contribute even a small sum, it would be possible to supply the necessary food, drugs, and clothing. Do not hesitate because your check is not as large as you would like it to be. Contributions of any amount will be welcome.

Every cent given will be economically spent for supplies for Belgian physicians and their families. There are no charges for shipping and distribution. Not a cent of the contributions received has been spent for stenographer, stationery, stamps, etc. The following contributions were received during the week ending February 13, 1915:

Dr. O. O. Cooper, Hinton, W. Va.	$10.00
Dr. F. A. Dodge, Le Sueur, Minn.	10.00
Dr. Alfred A. Herzfeld, New York, N. Y.	10.00
Dr. A. W. Sieker, Plymouth, Wis.	5.00
Dr Charles H. Cargile, Bentonville, Ark.	10.00
Dr. A. A. Bornscheuer, Pittsburgh, Pa.	2.00
Dr. Lyn Waller Deichler, Philadelphia, Pa.	5.00
Dr. H. T. Goodwin, New York, N. Y.	5.00
Dr. Henry S. Weigle, Muncy, Pa.	5.00
Dr. James S. Keyes, Brooklyn, N. Y.	5.00
Dr. J. I. Johnston, Pittsburgh, Pa.	15.00
Dr. Frederick J. Russeguie, Saratoga Springs, N. Y.	10.00
Dr. Frank H. Jackson, Houlton, Me.	5.00
Dr. Howard L. Frost, Cleveland, Ohio.	10.00
Dr. H. St. L. Moncure, Norfolk, Va.	5.00
Dr. A. J. Braden, Duluth, Minn.	5.00
Dr. Wendell C. Phillips, New York, N. Y.	75.00
Dr. Russell S. Fowler, Brooklyn, N. Y.	25.00
Dr. John W. Farlow, Boston, Mass.	25.00
Dr. E. W. Link, Palestine, Texas.	10.00
Dr. H. R. Link, Palestine, Texas.	5.00
Dr. H. Gifford, Omaha, Nebr.	100.00
Jefferson County Medical Society, Birmingham, Ala.	50.00
Dr. Edgar R. McGuire, Buffalo, N. Y.	10.00
Dr. Max Einhorn, New York, N. Y.	25.00
Dr. Joseph L. Miller, Thomas, W. Va.	10.00
Dr. David Chester Brown, Danbury, Conn.	10.00
Oshkosh Medical Club, Oshkosh, Wis.	50.00
Dr. George M. Dill, Prescott, Wis.	1.00
Camden County Medical Society, Camden, N. J.	50.00
Dr. Joseph Walsh, Philadelphia, Pa.	10.00
Dr L. B. Pilsbury, Lincoln, Nebr.	5.00
Dr E. E. Montgomery, Philadelphia, Pa.	25.00
Dr. J. T. Clegg, Siloam Springs, Ark.	1.00
Dr. K. B. Huffman, Bentonville, Ark.	1.00
Receipts for week ending Feb. 13th.	$605.00
Previously reported receipts.	2,528.00
Total receipts	$3,133.00
Previously reported disbursements	$2,530.00
Disbursements week ending Feb. 13th, 275 boxes of food at $2.20 per box	605.00
Total disbursements	$3,135.00
Deficit	$2.00

F. F. Simpson, M.D.,
Treasurer.

The Death Rate in 1913.—The statistics published recently by the Census Bureau show that in the registration area of the United States in 1913 with an estimated population of 63,298,718, covering twenty-four States, there were 890,848 deaths. Deaths in 1913 showed a slight increase over 1912 and were at an average of 14.1 per thousand of population. Following are the rates for the States included within the registration area: California, 14.5; Colorado, 11.5; Connecticut, 15; Indiana, 13.3; Kentucky, 13.3; Maine, 15.3; Maryland, 16.2; Massachusetts, 15; Michigan, 16.3; Minnesota, 15.4; Missouri, 12.5; Montana, 12; New Hampshire, 17.1; New Jersey, 14.3; New York, 15; North Carolina (figures relate only to municipalities having a population of 1,000 or over in 1900), 16.8; Ohio, 13.8; Pennsylvania, 14.6; Rhode Island, 15; Utah, 11; Vermont, 15.8; Virginia, 13.9; Washington, 8.5, and Wisconsin, 11.5. The lowest death rate shown by any registration State was that for Washington, 8.5 per 1,000, while New Hampshire's rate, 17.1, was the highest. The death rate per thousand of population in New York City in 1913 was 14.3, Rochester 14.6, Syracuse 15.7, Albany 19, Buffalo 15.8. Chicago was 15.1, Boston 16.4, Philadelphia 15.7, Pittsburgh 17.1, Baltimore 18, Newark 14.4.

New York City Death Rate.—There were 1,464 deaths and a death rate of 13.15 per 1,000 of the population during the week ending February 6 as against 1,503 deaths and a rate of 14.04 during the corresponding week in 1914, a decrease in the absolute number of deaths of 39, and in the rate of .89 of a point, which is equivalent to a relative decrease of 99 deaths.

Automobile Accidents in Connecticut.—There were eighty-eight automobile fatalities last year in the State of Connecticut, according to figures published by the Secretary of State. This is an increase of eighteen over the year previous.

Killed by the Italian Earthquake.—According to figures given out in Rome, 24,203 persons perished in the recent earthquake. At Avezzano the dead numbered 10,719, which is 96 per cent. of the population of the town. In the entire province of Aquila, in which Avezzano is situated, 23,747 persons lost their lives.

The Need of a State Sanitary Code.—The New York State Public Health Council has transmitted a report of its work to the Governor, in which it points out the necessity for a State sanitary code. The duty of enacting sanitary regulations has been exercised by 1,438 local boards of health, making it possible to have that many sets of rules, yet the health commission which framed the present health law discovered that many communities had no sanitary code whatever.

Clearing House for Mental Defectives.—Charities Commissioner Kingsbury of this city has appointed the following committee to consider the plans of Dr. Schlapp for a clearing house for mental defectives: Dr. Charles L. Dana, chairman; Dr. Thomas W. Salmon, vice-chairman and secretary; Mrs. William K. Vanderbilt, Mrs. Charles Dana Gibson, Judge Franklin C. Hoyt, Franklin B. Kirkbridge, Prof. Stephen P. Duggan, Prof. Robert S.

Woodworth, Dr. William L. Russell, Raymond B. Fosdick, and Dr. Walter Fernald.

The High Cost of Radium.—The chief of the Bureau of Mines was recently strongly criticized for failing to make good his promise to turn out radium at one-third of the present market price of $120 a milligram. Instead of producing it at a 30 per cent. decrease, the critic said, it had cost 200 per cent. above the market price, and moreover the bureau had failed in its promise to produce a greatly increased quantity.

The Texas State Board of Medical Examiners.—At a meeting of this Board, held at Waco, February 4, the following officers were elected: *President*, Dr. T. J. Crowe, Dallas; *Vice-President*, Dr. M. F. Bettencourt, Mart; *Secretary-Treasurer*, Dr. M. P. McElhannon, Belton. The Board is composed of the following members: Drs. J. J. Williams, Groesbeck; M. F. Bettencourt, Mart; H. B. Mason, J. S. McCelvey, Temple; M. P. McElhannon, Belton; J. H. McLean, Fort Worth; W. C. Swain, Dallas; Morrow, Austin, Crowe, and Scothorne, Dallas.

Civil Service Examinations.—Open competitive examinations for the following positions in the New York State Department of Health will be held in various cities throughout the State, February 27, 1915: (1) Director, Division of Communicable Diseases, salary $4,000. Open to men only. Applicants must be physicians of not less than five years' standing, and, when appointed, shall not be over sixty years of age; they must also submit evidence satisfactory to the Public Health Council or to a duly authorized committee thereof, that they have had not less than five years' experience in those phases of public health work which relate to the cause, prevention, and control of communicable diseases. (2) Director, Division of Public Health Nursing, salary $2,500. Open to women only. Applicants must be either physicians or registered nurses; they must also submit evidence satisfactory to the Public Health Council or a duly authorized committee thereof, that they have had not less than three years' suitable administrative and practical experience in one or more of the following subjects: (*a*) Obstetrics, (*b*) Infant Welfare, (*c*) Social Service, (*d*) Tuberculosis, (*e*) Communicable Diseases, (*f*) School Nursing. The examinations are open to residents and non-residents without restriction, but all candidates must be full citizens of the United States.

On February 27 an examination will be held for Superintendent of the Onondaga County Tuberculosis Hospital (just outside the city of Syracuse), salary $2,500 and maintenance for superintendent and family; and in March 6 for Superintendent of the Oswego County Tuberculosis Hospital (Orwell, N. Y.), salary $1,200 and maintenance. These examinations are open only to male physicians who are licensed to practise in New York State and who have had at least three years' experience in the practise of medicine.

Application blanks for any of these examinations may be obtained from the State Civil Service Commission, Albany, N. Y.

Dr. Henry S. Oppenheimer has removed to 276 Madison avenue, New York.

Dr. Nicholas A. Gallagher has been appointed city physician of Malden, Mass.

Dr. Francis X. Dercum of Philadelphia has been appointed Consulting Physician to the State Hospital for the Chronic Insane at Fairview, Pa.

The "American Practitioner" has been purchased by the Urologic Publishing Association and consolidated with the *American Journal of Urology, Venereal and Sexual Diseases*. The consolidated journal will be under the editorship of Dr. William J. Robinson. The publication offices will be at 12 Mt. Morris Park West, New York City.

Harvey Society Lectures.—The ninth lecture of the series will be given at the New York Academy of Medicine, 17 West Forty-third street, on Saturday evening, February 27, at 8.30 P.M., by Prof. R. R. Bensley, University of Chicago. Subject: "Structure and Relationships of the Islets of Langerhans and Criteria of Histological Control in Experiments on the Pancreas."

National Control of the New York Quarantine.—The Committee on Public Health of the New York Academy of Medicine has sent a letter to Governor Whitman urging the transfer of the quarantine station at this port to the national government. The letter suggests that now would be an opportune time to make the transfer as the term of the present quarantine officer expires this month. During the past two years it is said to have cost the State nearly $100,000 a year above receipts to maintain the quarantine station.

Osteopaths Barred from Practice.—The finding of Dr. D. Webb Granberry of East Orange, the osteopathic member of the New Jersey State Board of Medical Examiners, who refused to sanction the licensing of graduates of the extinct College of Osteopathy in Passaic to practise osteopathy, has been sustained by the full Board. This bars from license about ninety graduates of the institution who threaten now to appeal to the courts for a mandamus.

Obituary Notes.—Dr. JOSEPH KALISHER of New York, a graduate of the New York University Medical College in 1881, and a member of the American Medical Association and the New York State and County Medical Societies, died at his home on January 27, aged 56 years.

Dr. LESLIE HOWARD EVANS of Hebron, Me., a graduate of the University of Vermont, College of Medicine, Burlington, in 1912, and assistant physician and pathologist at the Maine State Sanatorium, died at the Central Maine General Hospital, Lewiston, on January 17, aged 35 years.

Dr. WILLIAM J. SHEEHAN of New Haven, Conn., a graduate of the Medical Department of Yale University in 1895, a member of the American Medical Association and the Connecticut State Medical Society, and vice-president of the New Haven Medical Society, died at St. Raphael's Hospital, New Haven, after a short illness from septic poisoning, on January 13, aged 44 years.

Dr. JAMES MORRISON BODINE of Louisville, Ky., a graduate of the Kentucky School of Medicine, Louisville, in 1854, formerly dean and professor of anatomy in the University of Louisville, Medical Department, and a member of the American Medical Association, the Kentucky State Medical Association, and the Jefferson County Medical Society, died at his home on January 25, aged 84 years.

Dr. ANDREW DICKSON PACKER of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1908, and surgeon to the Long Island College Dispensary, died at his home, on February 1, aged 35 years.

Dr. ALONZO B. HUGHES of Keokuk, Ia., a graduate of the College of Physicians and Surgeons, Keokuk, in 1897, and a member of the Iowa State and Lee County Medical Societies, died at his home, on January 17, aged 57 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CHADWICK MEDALS AND PRIZES AWARDED—SANITARY STATE OF EXPEDITIONARY FORCE—TYPHOID INOCULATION—HABITUAL DRUGGING—MOTOR LABORATORY—OBITUARY.

LONDON, January 29, 1915.

THE Chadwick medals and prizes of £50 each to the naval and military officers who have most distinguished themselves in promoting the health of these services were presented at the second Chadwick lecture as I informed you they would be, Sir W. J. Collins again presiding. He explained that the Chadwick trustees were availing themselves for the first time of their optional power to offer these distinctions. Sir Arthur May, medical director general of the navy, introduced Fleet Surgeon R. C. Munday as the officer selected on behalf of his service and remarked that very few people knew how enormously the health of the navy had improved in the last thirty-five years. The sick rate per 1,000 in 1878 was 47 per day; now it is 25. The death rate was then 6; to-day only 2. If the sick rate had continued undiminished they would be having every day 5,000 more men on the sick list. The improvement placed in the fighting line no less than the crews of seven dreadnoughts—an achievement of hygienic measures.

The recipient for the army service was Colonel W. H. Horrocks, who was introduced by Sir Alfred Keogh, medical director-general. He said the colonel was responsible for the health of the army in France and was specially well known for his success in dealing with Malta fever, which used to strike down 600 to 700 men every year. To-day there is no expense due to that for there is no fever at Malta. Sir W. J. Collins then presented the medals and prizes, after which Dr. F. M. Sandwith delivered his second Chadwick lecture.

Sir F. Treves on taking the chair at a Chadwick lecture made an important statement as to the sanitary state of the British expeditionary force. Speaking with experience in the South African and Russo-Japanese wars he declared the present sanitary arrangements were without parallel for the measures carried out to secure the health of the soldiers and to care for them when attacked by disease. But he went on to say that though typhoid could thus be immensely lessened, an additional precaution was needed against it and that was afforded by inoculation. This truth, he emphatically asserted, admitted of no doubt. The results in the expeditionary force had been astonishing. Before the war there had been 212 cases of typhoid, of which 201 were unprotected, for 173 out of the 201 had never been inoculated, 28 had received a single inoculation or had not received any for over 2 years. Out of the 212, only 11 had been inoculated, and there were 22 deaths, none of whom had been inoculated. In the whole force not a single man who had been inoculated had died of typhoid. Sir F. Treves considered the figures left nothing to be said and those who tried to persuade men against inoculation were playing into the hands of the enemy, who would give the same advice. He remarked further on the revolution in the transport service shown in the present war—a motor laboratory, motor ambulances, and motor kitchens having been supplied up to the front. But he thought we should never be able to dispense at the actual firing lines with the horse ambulance; for a motor could get into a ditch but could not get out. A horse could. Besides, a motor could not travel a whole day with a column, *i.e.* owing to gearing could not travel at three miles an hour for 12 hours.

Sir William Osler, regius professor of medicine at Oxford, on Wednesday evening addressed the officers and men of light infantry stationed there on typhoid fever. He wore a colonel's uniform and began by saying this disease had been for above a century a terrible scourge of armies. He hoped they would not listen to the cranks who were circulating statements against inoculation. The question was perfectly plain—were they to be led by a set of misguided and ignorant cranks, such as anti-vaccinationists and other antis, whose literature showed the profoundest ignorance of everything that had been proven in scientific medicine and everything going on during the last half century? It was appalling to think that people who did not lack intelligence should be in ignorance so abysmal as was displayed in the literature distributed by their societies.

Much has been written about the evil effects of the drug habit, and lately the injury to the mental power of those indulging in it is again coming forward. Last summer Dr. Armstrong Jones presented in a newspaper a vivid picture of brilliant careers wrecked and families reduced from affluence to pauperism through this habit. His presentation of the subject elicited a reply from Dr. Stansfield, who denied that mental derangement was so frequently due to this habit as is constantly represented and appealed to the records of lunatic asylums in support of his view

In the one in which Dr. Jones himself resides he found only six cases recorded as thus caused in 20 years. In Dr. Stansfield's institution he has full notes of 8,404 cases admitted and among them only nine in which the drug habit was considered to be the exciting or predisposing factor in the causation.

Reports of the Commissioners in Lunacy are quoted which corroborate these statements. The habit is certainly to be depreciated but facts need not be misrepresented to enforce the lesson of its danger.

I told you about our motor ambulances and operating theater at the front. A very important addition has been made, viz. a motor laboratory presented to the war office by an anonymous donor and named after Princess Christian. It is equipped with the most approved appliances and cannot fail to be of service to the medical staff. This motor bacteriological laboratory seems well designed and complete. Attached to it is a motorcycle with sidecar. This will go right forward to the field and bring back to the laboratory stationed at the base samples for investigation. The car is from 20 to 30 horsepower and cost £2,000.

Deputy Surgeon-General George Alder Watson of the Indian Medical Service, has died at the age of 83. He served in the Crimean War at the seige of Sebastopol, in the Indian Mutiny at Inhow and the Siege of Dhar. He was also with the Afghan Field Force in the advance on Kandahar and was awarded the medal. He qualified in 1853 and retired from the army in 1885.

Dr. Burney Yeo, whose death I reported to you in November, left a fortune of above £90,000, most of which he bequeathed to institutions for the benefit of the profession.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

TREATMENT OF CHOLERA—EPIDEMIC CYCLES OF VARYING SEVERITY—INSPECTION OF HEALTH CONDITIONS IN THE INTERIOR—FILIPINO RED CROSS PROJECT ABANDONED—DISAPPEARANCE OF THE CHOLERA—A SANITARY COMPANY FOR EMERGENCIES.

MANILA, December 20, 1914.

AN excellent paper by Drs. A. P. Goff and O. E. Denney, in charge of the cholera wards at San Lazaro Hospital, was recently read before the Philippine Islands Medical Society, based on the 330 cases of cholera which came under treatment. Of this number, 72.5 per cent. recovered, which is an unusually high proportion. Ultimate decision as to diagnosis rested in the bacteriological findings of the Bureau of Science. The course of the outbreak was unusual in that a group of patients gravely ill was followed by one less ill, and then with a group presenting but a few mild symptoms of the disease. This cycle repeated itself throughout the outbreak. These groups did not come from any one source of infection, but were made up of cases widely scattered. Of the cases admitted, 56 per cent. were violently ill, and of these 61 cases needed emergency treatment. As a diagnostic sign, the authors point out that all acutely ill patients sleep with their eyes partly open, two-thirds of the pupil being visible. This was regarded as significant in border line cases awaiting bacteriological diagnosis. Treatment was based on the restoration of body fluid and prevention of nephritis. Intravenous injections of 0.45 per cent. sodium chloride and 0.25 per cent. sodium bicarbonate were used, the fluid entering the veins at the rate of about 1 liter in 45 minutes. Sometimes as much as 10 or 12 liters were given in 24 hours. Given slowly, cramps and vomiting were avoided, and usually a quiet sleep followed. No infections occurred. Proctoclysis was also used with excellent results. One case recovered after complete suppression of urine for 96 hours. The average duration of illness in fatal cases was 72 hours; of convalescence, comprising disappearance of all symptoms and two negative examinations of stools, 13 days. Most pregnant women aborted.

For the purpose of investigating health conditions in the Mountain Province, with a view of formulating plans for the furtherance of health, sanitation and general welfare of the uncivilized hill people, Major E. L. Munson, who has been acting as advisor in health and sanitation to the Government of the Philippines, will leave for the Mountain Province to spend at least a month and make a horseback trip of some 400 miles. He will leave Manila immediately on the return of Dr. Heiser. There has been a considerable addition to the sanitary personnel sent to the uncivilized people within the past few months, and the Secretary of the Interior is desirous of extending medical facilities among them as rapidly as possible. Some little difficulty has been encountered, however, in finding doctors and sanitary inspectors willing to work among them. Plans are under way to train a number of Igorotes for work among their own people, and several Moros have recently been entered for the course in the Training School for Nurses, with a view to their return to take up medical work in the hospitals of the Moro country.

The proposition to send a Red Cross party, composed exclusively of Filipino doctors and nurses to the European war has fallen through, as the American National Red Cross Society cabled that only persons born in the United States, and speaking a language of one of the belligerents other than their own, would be considered. The movement had already attained considerable magnitude, the local society had appropriated 10,000 pesos as a start for the fund, a subscription list was to be opened in each province by the Governor, the Filipino "Boy Scouts" were to institute a "Tag Day," and other auxiliary measures were being considered.

Cholera in Manila has been completely eradicated, and only a few sporadic cases are occurring in a few places in the provinces, where it is completely under control. It is expected that it will have been entirely suppressed within two or three weeks. In Manila the systematic examination of non-suspects for cholera, which has been made at the rate of some 2,000 per day, was discontinued a fortnight ago, as nearly two weeks had passed and nearly 25,000 examinations made without discovering a carrier. The force of emergency sanitary employees is being called in to Manila and will be largely discharged in the next few days. A plan has been worked out, however, to form a sanitary company which will be maintained as a reserve to meet emergencies arising from cholera, plague, smallpox, etc. When no emergency exists, the personnel is to do routine work in vaccinating, the sanitation of provincial towns, the education in sanitary matters of the uncivilized people, etc. The proposed organization is to have one senior health officer in charge, four junior health officers as assistants, four sanitary inspectors, eight senior assistant sanitary inspectors, and thirty-two assistant sanitary inspectors. This gives a total personnel of forty-nine, divided into four sections of one doctor, one sanitary inspector, two senior assistant sanitary inspectors, and eight assistant sanitary inspectors. These sections are of convenient size to operate independently, or they may be aggregated into larger groups or the full company, as emergency may demand. The men are to be carefully trained and selected, and be paid somewhat better than others of similar grades. On an epidemic starting up in the provinces, the plan is to have one or more sections take over the situation, using the provincial and municipal sanitary personnel merely as assistants. Experience has demonstrated that no provincial organization can be expected by itself to cope successfully with any situation of real gravity.

7. Report of a Case of Congenital Multiple Cystic Disease of the Kidneys in Which One Kidney was Removed. F. S. Watson.
8. A Cheap Electric Heater. E. von Adelung.

1. Positive Skin Tuberculin Reactions in Children.—O. F. Rogers, Jr., has made a study of the subsequent history of 69 children who gave a positive von Pirquet reaction while in the Massachusetts General Hospital and who have been out of the hospital for an average of two years, four months. The results show that before the age of two a positive skin reaction seems to

be an indication that the child's life is likely to be short. The mortality among all children up to the age of 10, who react to the von Pirquet test is much higher than that of normal children.

2. Rupture of Intestine.—L. Davis reports two cases of this condition in children, aged respectively seven and eight years, in the one instance resulting from a fall and in the other resulting in the patient being struck down by an automobile. Both cases illustrate the well-known fact that operations for ruptured viscera to be successful must be prompt. In the first case reported, the margin of time elapsed since the accident had very nearly reached the limit of possible successful issue for that particular case. To wait until the diagnosis is certain in these cases is to court disaster. In cases of ruptured intestine, with effusion of septic contents, the author is convinced that profuse and thorough irrigation of the peritoneal cavity is a life-saving measure. There has been no time for walling off on the part of nature and hence there need be no fear of spreading the infection; it is an entirely different proposition from a peritonitis from an appendix, in which cases nature has practically always had some opportunity of localizing the process, and irrigation is to be condemned. The author has found that children and adults retain ordinary tap water by rectum as well as, if not better than, normal salt solution.

4. Congenital Pyloric Tumor.—C. L. Scudder has *x*-ray evidence of the persistence of pyloric stenosis in cases of this condition subjected to posterior gastrojejunostomy. The recognition of the persistence of the tumor in congenital pyloric stenosis is important for the following reasons: The tumor alone with the mucous membrane changes is an adequate cause of the obstruction in all its phases, and it is unnecessary to imagine a pyloric spasm associated with the obstructing tumor. The surgical treatment of these cases is without any question the only permanently effective treatment. The postponement of the operation with the idea, now so prevalent, that the hypothetical spasm will let up and the tumor disappear and the child recover is unjustifiable. A baby having tumor obstruction will always have tumor obstruction. The omission of the hypothetical pyloric spasm from any consideration in these cases will result in earlier adequate surgical relief.

5. Fat Indigestion.—C. H. Dunn summarizes the typical features of fat indigestion in infancy as an inability to gain weight without fat and an inability to gain with it. Chronic disease, particularly tuberculosis, is found associated with these cases with marked frequency. Long continued overfeeding may be the primary injury. One can only to a very slight extent compensate for the deficient power to digest and absorb fat by increasing the carbohydrate and protein. The microchemical examination of the stools for fat is a reliable guide in the feeding of these cases. In the treatment of severe cases of fat indigestion the mild modifications used must be low in fat, average in carbohydrate, comparatively high in protein. The extra sugar should be maltose. A certain number of the milder cases will do well on this treatment. Severe resistant cases are those which cannot gain on a low quantity of fat, and cannot tolerate an increase. A large number of cases are so severe and resistant that they can only be saved by human milk. Breast milk will save most of these cases, even the severe ones, if used in time. It should always be used in resistant cases, whenever it can be obtained. Even a little breast milk is of value and may save a case which would otherwise be fatal. After a period of breast milk feeding, many cases are found no longer severe and resistant to artificial feeding. If breast milk cannot be obtained, the feeding is very difficult and the outcome uncertain. Excessive increase of carbohydrate or protein will not help these severe cases, and may do harm; not more than 7 per cent. carbohydrate or 3 per cent. protein, should be given. Whey mixtures are of no help, except sometimes in very young babies, who vomit curds; they may do harm. Giving the protein in the form of precipitated casein may be tried, and may help in some cases. There is not sufficient evidence of its value to indicate its use as a routine.

6. Acute and Chronic Empyema.—W. Whittemore has studied the end results of the cases of acute and chronic empyema operated on at the Massachusetts General Hospital during a period of ten years. The mortality in acute empyema was 20 per cent. Many of the bad results are caused by the fact that the diagnosis is not made early enough and that the operation is not done soon enough. One should operate when aspiration shows the serum to have a good many leucocytes in it rather than wait until it becomes pus. A good many cases are not drained at the bottom of the cavity so that there is a certain collection of pus that does not drain easily. If in exploring a cavity through the first incision one is not at the bottom, a second incision should be made, provided the patient's condition allows it.

7. Nose, Throat, and Ear Conditions. R. B. Scarlett.
8. The Urine in Old Age. H. Greeley.
9. Chronic Parenchymatous Nephritis with Myocarditis. H. A. Fisher.

1. Active Immunization in Hay Fever.—S. Oppenheimer and M. J. Gottlieb immunize their hay-fever patients by injecting gradually increasing doses of pollen extract to produce tolerance to the anaphylatoxin formed in the body. Beginning with one to five units of pollen extract, the dose is gradually increased until a local reaction appears at the site of the injection. This dose is then continued until the patient shows no more reaction. Then the dose is gradually increased as before. One unit of pollen toxin is the amount of antigen dissolved in one cubic centimeter of extract at a dilution of one to twenty millions.

5. Digitalis Therapy.—S. Neuhof points out that the best single criterion of the amount and duration of digitalis administration is its clinical effect. The beneficial effect of digitalis depends chiefly upon producing increased contractile power of the cardiac musculature. The slow production of arrhythmias is usually coincident with full clinical effects of the drug. If decompensation demands the continuance of digitalis, the rapid onset of arrhythmias does not contraindicate its further use. Atropine sulphate 1/150 to 1/100 grain three times a day, given internally or subcutaneously at the beginning of medication, occasionally prevents nausean and vomiting in susceptible individuals. The hypertension of cardiovascular disease does not contraindicate the use of digitalis. To derive clinical benefits quickly, digitalis should be given in full therapeutic doses. When digitalis acts promptly in small doses, the effect is likely to be temporary. For permanent improvement long continued medication is usually required. Digitalis occasionally produces epigastric pressure sensitiveness, and "hunger pains" which appear to

be due to heightened vagal tone. These symptoms precede vomiting by one or two days and indicate a full therapeutic digitalis effect. This epigastric pressure sensitiveness must be carefully distinguished from that sometimes caused by cardiac decompensation.

8. The Urine in Old Age.—H. Greeley states that microorganisms found in the nasal mucosa may frequently be obtained from the urine and that this may be the result either of excretion processes or, as seems more probable, to a common specifically lowered resistance of the individual in parts of the body favorable for the growth of the microorganisms. The latter include enterococci, diphtheroids, streptococci, colon bacilli, Friedländer's bacillus, aorsporidia and pathogenic yeasts.

2. Operation for Cerebral Spastic Paralysis. — W. Sharpe and B. F. Farrell report a method of surgical treatment for spastic paralysis, performed in sixty-five cases selected from a total of 201 cases of this condition. In these cases of the hemiplegic, paraplegic, or diplegic type, with a definite history of difficult labor with or without the use of instruments, in which, on ophthalmoscopic examination, signs of intracranial pressure are shown in the dilated retinal veins and a blurring and haziness of the optic disks, especially of their nasal halves, a large right subtemporal decompression is performed to relieve the intracranial pressure. If the intracranial pressure is extremely high and remains high after the operation, a left subtemporal decompression is performed the following week, the operative recovery requiring only a week or ten days. The operation itself consists of a vertical incision over the side of the head from 2½ to 3 inches in length, extending from the parietal crest down to a point overlying the zygomatic arch and just anterior to the external auditory meatus; that is, to the lowermost point of the cranial cavity. The fibers of the temporal muscle are separated longitudinally and then a small opening in the squamous bone, made by the Doyen perforator and burr, is enlarged by rongeurs to a diameter of from 2 to 3 inches. The dura is now incised in a stellate manner, allowing the brain to expand, and in this way the increased intracranial pressure is relieved. The dura is *not* resutured and the bone is not replaced. The usual pathological findings are definite supracortical fibrous or cystic formations resulting from a cortical hemorrhage occurring at birth. These lesions are treated according to the individual findings—removed, punctured, the interior touched with some mild corrosive to cause an obliteration (great care being taken that no excess of the corrosive fluid escapes over the cortex), and very frequently, merely let alone; that is, more damage to the cortical cells may be done by endeavoring to remove the lesion and therefore it is wiser not to attempt it. The decompression operation is performed merely to offset the effects of the pressure of this hemorrhage with cystic formation, and the resulting spasticity and mental impairment. The after-treatment consists in the correction of deformities by tendon lengthenings if necessary, or merely stretchings of the contracted muscles, the maintenance of corrected positions through the employment of especially adapted braces, skilled massage and faradism, particular attention being given to the weakened and overstretched muscle groups. A careful, systematic course in muscle training is carried on daily. The improvement in the author's cases selected for operation was marked not only by a lessening of the spasticity, but also by a definite amelioration of the mental condition of the patient.

4. Sensitized Vaccines in Typhoid Fever. — A. L. Garbat has found that the treatment of typhoid fever by sensitized typhoid bacteria offers a more rational therapy from an immunological point of view than by the ordinary non-sensitized vaccine. The repeated inoculation of large doses of sensitized vaccine even in very sick patients, was not attended by any harmful effects or a distinct negative phase; the general course of the disease seemed milder and the complications less; the occurrence of a crisis in the infection took place in a small percentage of cases, the improvement usually being gradual. Perhaps more striking results will be attained by the use of more frequently repeated and smaller doses.

7. Effect of Gravity on the Fetus. — C. G. Barnum believes that it has been shown that the action of gravity contributes to the production of the cephalic presentation, and that the interpretation of Schatz' experiments was an error because of the manner in which the support was applied in those experiments. In support of the proposition that the action of gravity participates in the determination of the cephalic presentation, three main considerations are brought forward: (1) The amount and distribution of the effective part of the weight of the fetus lying in the amniotic fluid. (2) The admitted contribution of the action of gravity to the production of the left occipito-anterior position, which is one of the most characteristic features of the cephalic presentation. (3) The very great probability that the action of gravity contributes to the production of the normal cephalic presentation and the normal position of the fetus in animals.

9. Quinine Bisulphate in Bladder Irrigation.—E. McDonald states that the requisite of an irrigating solution in cystitis in women is that it should be non-irritating, easily obtained, antisetic, and stimulating and healing to the inflamed surfaces. Of all the substances used by the author, quinine bisulphate is said to best fulfill these requirements. It is easily soluble in water, is comparatively non-irritating, and is distinctly antiseptic, much more so than the various irrigating solutions now generally used. It has a phenol coefficient of 0.5, inhibits the growth of a fresh typhoid culture in the strength of 1:30,000. It may be used in irrigating in a strength of 1:2,000 without noticeable irritation.

1. The Telephone Attachment in Surgery. Sir James Mackenzie Davidson.
2. Splenectomy for Enlarged Spleens with Anemia. G. Barling.

3. A Critical Study of the Basis of Abderhalden's Serum Reaction. W. E. Bullock.
4. Electrotherapy at a Base Hospital. W. J. Turrell.
5. Fear and Disease. E. T. Jensen.

1. **The Telephone Attachment in Surgery.** — Sir James Mackenzie Davidson advocates as a means of locating foreign bodies in wounds the use of a telephone, preferably with double receivers, connected together by means of a steel or elastic band, so that each ear has its separate receiver. This not only increases the intensity of the sound, but also serves to cut off extraneous sounds which might interfere with the audibleness of the telephone. Should the surgeon wish to have one ear uncovered so as to be able to attend to the remarks of anyone near him, it is quite a simple matter to move aside one of the receivers. This double arrangement, however, is not essential, and a single telephone gives quite good results if the surgeon's hearing is acute. The carbon plate is placed upon the patient's moistened skin, and plaster or bandage may be used for holding it in position tightly against the skin. The other end of the telephone should have attached to it a bare wire, of silver preferably, which has been disinfected, by boiling or otherwise as the surgeon may direct. One end of this wire being attached to the telephone terminal, which of course cannot be disinfected readily, the other end need be handled only by the surgeon or his assistant with the usual antiseptic precautions, and the wire can either be wound round any instrument it is desired to use, or, a spring clip may be employed by means of which the wire can be conveniently brought into connection with the knife, probe, needle, or forceps, as the case may be. Under these conditions, if the instrument is introduced into the body it will, on first contact with any metal, give rise to an unmistakable click carried through the telephone, and then, if it be gently moved or slightly disturbed so as to make a rubbing contact with the foreign body, an equally unmistakable loud rattle will be elicited. By such means the metal can be dissected out (if the knife is used), or otherwise freed from the encircling tissues, because a constant control can be exercised over the foreign body by reason of the microphonic rattle it produces when the instrument comes into contact with it. A very useful point to bear in mind is that in cases where a foreign body has been carefully localized by means of *x*-rays, a needle can be attached to the telephone in the manner stated, run down on to the foreign body, and, when the characteristic sound is heard, can be maintained in its position as a guide before any incision is made. The telephone arrangement has a special utility in ophthalmic surgery.

3. **The Basis of the Abderhalden Reaction.**—W. E. Bullock has not been able to cause the production in rabbits of a ferment which digests coagulated egg white by the injection subcutaneously, intraperitoneally, or intravenously of raw egg white. A minute quantity of amino-acids is present in 10 c.c. of blood serum of rabbits and dogs, and it was found (in rabbits) that after a bleeding these substances are increased in amount. An autolytic ferment is found in the blood serum of rabbits, dogs, and in human serum. The serum of the pregnant rabbit is unable to break down rabbit placenta, and the serum of the pregnant bitch is unable to break down dog placenta. Human blood serum from the pregnant female and from the healthy male, incubated with human placenta, produced by chemical or physical action amino-acids. Rat blood serum ("normal" and "tumor") breaks down rat tumor. Guinea-pig serum ("normal" and "tumor") breaks down guinea-pig tumor and mouse tumor. The blood serum of the guinea-pig is not rendered more active in this property by a previous inoculation of the animal with mouse tumor. The method devised by Abderhalden, even with technical improvements, is thus seen to be inadequate to distinguish normal from pregnant or cancerous sera. The fundamental experiments adduced by Abderhalden do not, on repetition, give the results stated by him, and a proteolytic ferment normally present in the serum of mammals acting on tissue substrates of varying lability, prepared in accordance with his directions, in all probability accounts for his results and their confirmation by others.

5. **Fear and Disease.** — E. T. Jensen believes that apart from the consideration of the eliminating capacity, which may here be assumed to be more or less constant for the individual, toxemia from the alimentary tract has always two factors—the chemical, comprising the toxins themselves, and the vital, dealing with the resisting power of the individual. This resisting power depends on the tone of the viscera and is powerfully influenced by the subjects' state of mind. Further, this tone may well be part of a condition which should be normally shared by the entire musculature of the body. This apparently explains adequately why the active are, as a class, more healthy than the sedentary. If fear can paralyze the hollow viscera, it must follow that happiness and courage can, to some extent at least, cause them to contract and check toxic absorption. This would constitute a link between mind and body by which the power of suggestion is transmitted to the organism. Thus may some of the cures by Christian and allied "sciences" be explained, and improvement in health follow improvement in circumstances, be these affairs of heart or pocket.

The Vita Sexualis and Warfare.—Touton discusses one of the oldest subjects of the world. Warfare and "free love" have always gone hand in hand. The soldiers have their own camp followers and also appropriate the females of the conquered foe. Victorious campaigns are also followed by eras of promiscuous love. The old Asiatic soldiers took their concubines along, thereby doubling the equipment; but in case of victory sometimes found it more profitable to choose a concubine from the defeated, who had a good wardrobe of her own. Some soldiers declared that they could always fight more desperately if there was a woman awaiting them at the rear. The Jews would allow no women within the camp and those in the rear were at least nominally employed with military duties. The Greek commanders at Troy quarrelled over beautiful captives. The first step before a battle among the later Greeks was to always to place their concubines in a position of safety, a non-sublimated "ladies first." Alexander the Great abolished the custom of camp followers, but after the conquest of Persia the victors took concubines from the defeated. Rome, in the Empire, did not allow her soldiers to marry and prohibited camp following by Roman girls. The intense activities of the troops naturally had an anaphrodisiac effect. Hannibal's unsuccess in Italy was due largely to the fact that during his 16 years of occupation, very many of his soldiers formed relations with the native women. Some great Roman generals began their campaigns by driving away the concubines, who before one battle had numbered 2,000. It is evident, however, that while camp following was prohibited for Roman maidens there was no serious opposition to the presence of foreign women who settled in tents, etc., near the camp. When on leave of absence the soldiers visited them, but marriages were forbidden. That the cru-

sades did not better succeed was due to the relatively great number of loose women present. Some dressed as men, others as nuns, all posing as pilgrims. Some fought in the ranks. During the periods of siege immorality broke out in such a degree that women were flogged and branded. In the more successful crusades all women were kept out of the army, but on its arrival in Asia segregation became impossible. In the wars of the Middle Ages we find alternate periods of license and persecution in respect to women camp followers. At the close of the XV century the presence of venereal disease among the soldiers and prostitutes introduced a new argument, had one been necessary, against the alliance between soldiers and prostitutes. At this period, and probably for centuries before, any idea of concubinage must have disappeared and the women are always termed public prostitutes. At the time of the Thirty Years War we see attempts at regulation. A certain number of girls only were allowed to each company of soldiers, while the former showed evidences of organization and policed themselves. In certain campaigns and sieges the number of women was almost incredible and these with the male camp followers all had to be fed and transported with their baggage. In times of reaction all foreign prostitutes were threatened with amputation of the nose, and soldiers were encouraged to marry, the presence of their wives not being prohibited. The institution of soldiers' wives, however, only led to intense misery and hardship for the latter and their children. In certain localities soldiers had brothels in their barracks, the women making a pretense of running a sort of canteen for the sale of coffee. They paid a tax voluntarily. Napoleon, as might have been expected, came out strongly against prostitution. His original way out of it was imprisonment of women as a necessary measure to prevent venereal disease in his men. This program was impracticable, however, save under favorable conditions, and an attempt was made to register and examine the women for contagious disease. In Berlin alone, with a then population of 100,000, Napoleon's officers rounded up nearly 1,200 prostitutes, of which only one-third were registered. In more recent warfare, with every effort to protect the troops, brothels have been tolerated. In Mexico at present, soldiers and their wives often fight side by side. The author concludes that the attempts to separate men and women during warfare has never succeeded and never will.

Pneumococcus Angina and Its Treatment. — Leshke describes three clinical types of this affection: 1. Follicular, an ordinary follicular tonsillitis. 2. Angina which accompanies pneumococcus influenza. 3. Septic angina and general sepsis due to pneumococci. In the latter the local symptoms show no marked seriousness as compared with the ordinary follicular form and indeed may be so mild that the origin of the sepsis may be quite overlooked. The cultivation of pneumococci from the tonsillar crypts and blood establishes the diagnosis. The author relates a case each of pneumococcus sore throat with general reaction and pneumococcus sepsis. The author appears to regard severe angina with a general reaction (the first type) as differing only in degree from pneumococcus influenza complicated by angina. The former as compared with other forms of acute tonsillitis runs a rather protracted course, and is accompanied by an influenza-like reaction. In the simple form, however, we see follicular plugs and even a deposit while the angina in pneumococcus influenza is usually bright red and velvety. The author treats all these pneumococcus affections with ethylhydrocuprein, now sold under a proprietary name.

Etiology of Endocarditis Verrucosa.—Reye concludes his serial article as follows: the affection is always of bacterial origin whether occurring alone or with general rheumatism. The probable cause is a streptococcus anerobe, and the one heretofore known as the *S. mitior* or *S. viridans*, the alleged cause of endocarditis lenta, Hence the same microorganism may be able to cause two processes differing widely in the clinic. This duality is probably based on differences in the resisting power.

Tetanus in Wounded Soldiers.—Madelung has collected from hospital reports, correspondence, etc., a series of 27,677 wounded of whom 174 (6.6 per thousand) developed tetanus. The majority of these cases came from the Vosges Mountains campaign. In 80 cases the projectiles were infantry bullets, in 27 cases shrapnel bullets, and in 53 cases shell fragments. The wounds occurred in nearly all localities, the lungs being an exception. The author's notes on the outcome of the disease control 166 cases of which number 51 recovered and 115 died. In other words the mortality was 69 per cent. While this figure is a notable improvement over that in older warfare, analysis shows that with our theoretically available resources it could have been made smaller. Many patients received no prophylactic inoculation, many received much too little serum, and some got none at all. But three patients received magnesium sulphate and all recovered.

Snowblindness in Troops. — According to Gross this condition was well marked in the Napoleonic wars of 1812, the soldiers who returned home suffering freely from reddened eyes and obscured vision. The reflection of light from the snow causes a genuine ophthalmia, the eyelids and conjunctivæ being red and swollen. Blephorospasm is present, thus causing blindness. The sensations are extremely painful and disagreeable. Chemosis sometimes develops. The entire condition greatly resembles electrical ophthalmia. Despite its severity the condition yields to treatment and recovery should occur at the end of a fortnight. No statement is made as to whether the German troops are supplied with snow glasses.

January 5, 1915.

Clinical Signs of Beginning Heart Failure.—Moritz states that the mildest symptom of heart failure is insufficiency of movement when brought out by considerable muscular effort; while "insufficiency of rest" is the severest type. Here the patient lying supine and making no effort whatever shows evidences of cardiac failure. Between these extremes there is every degree of intensity and in chronic heart disease the organ passes from one degree to the other. In one sense of the term the force of the heart has never been measured; given units of time we cannot tell how much effort the heart makes in each unit. From another angle the behavior of the heart is under the influence of numerous separate factors. Our mainstay at present is to determine the disordered circulation which must result from cardiac insufficiency—the anomalous distribution of the blood-mass. Naturally a compensated heart is never an insufficient heart and must be left out of all calculations. A weakened left ventricle is first noticed clinically in the respiration, the back pressure causing pulmonary stasis. This may be manifested as a stasis-bronchitis with cough and eventually pulmonary edema. A weakened right ventricle on the contrary leads to congestion of the liver and dropsy, chiefly of gravitation. On the other hand palpitation,

pain and constriction over the chest, dyspnea may alike indicate cardiac weakness or mere nervousness. To distinguish between the two we can get much information from the pulse which is at least suggestive, the pulse beat in a general way being an index of the force of the cardiac systole. Normal volume with normal frequency naturally signify an efficent heart. The sphygmomanometer, on the contrary, does not give information as to cardiac force. In indicating increased blood pressure it only shows that the heart is doing an abnormal amount of work, a condition which if sufficently maintained may in time result in cardiac weakness. High blood pressure can thus be set up in a heart already weak and this state of affairs has naturally a grave prognosis. A quickened pulse as in Grave's disease may be evidence of cardiac failure. The family practitioner's method of testing the strength of the heart by sudden muscular exertion while of value may be the source of much falacy. The acceleration of the pulse is much less significant than failure of the pulse to drop to the normal within a reasonable time. Quite different is the behavior of the pulse after severe prolonged efforts, for an entire 24 hours may elapse before the pulse is quite normal. The author has recently studied this subject in soldiers after forced marches and the like and finds that tachycardia persists for relatively long periods.

Treatment of Tetanus.—Schneider reports a series of cases occurring in one of the Bavarian Military Hospitals. Individual experience is extremely misleading, and gives us no line on the general morbidity and mortality. In his hospital 22 cases have been treated since October 5, and in ten of these amputation or exarticulation had been performed in indication. In regard to the serotherapy of the disease the author thought it justifiable for the ulttimate good to use a parallel. Thirteen patients received the serum in sufficient dosage by the subcutaneous route and every one died, all but one within the first four days and the exception within the sixth day. These practically fulminant cases were not influenced at all by the serum. The author calls them insuccesses, but no treatment can be expected to save much life under the circumstances. In the other (nine) cases serum, was injected chiefly into a vein and three patients recovered while the rest, as a rule, showed improvement for a time. The severity of the disease was the same for each series. The high mortality in the combined material—3 recoveries in 22 cases—which coincides with the old mortality of the disease under narcotics, may have been due in part to the fact that nearly half the patients had just undergone amputation (or exarticulation); but in theory this fact should be turned in the other direction.

Deutsche medizinische Wochenschrift.

January 7, 1915.

The Utility of Vaccine Which Has Been Treated with Sulphuric Ether.—Voigt states that after vaccine has been sterilized with ether *a la* Fornet it may still give positive results, provided vaccination is performed immediately. But when vaccine thus treated is preserved even for a brief interval it can no longer be used for that purpose. If the vaccine-ether mixture is used *perse*, it retains its power for a longer period than when it has been dried. After vaccine has been freed from germs by ether, it may again become contaminated after ether evaporation, after drying and preservation, etc. It must be apparent therefore, that the ether principle is a detriment rather than an aid to vaccination.

Fatal Appendicitis from a Grazing Bullet.—Colley reports a case in which a bullet, which did not enter the abdominal cavity apparently aroused to activity a chronic appendicitis which had never caused symptoms. Death took place from peritonitis which was secondary to gangrenous appendicitis. The man had been struck in the chest wall—beteen sixth and seventh ribs at the anterior axillary line—apparently by two bullets, the entrance wounds being close together. No exit wounds could be found, and the only possible inference was that the projectiles had merely grazed the thorax. The double opening was the result. Immediately on being struck the officer collapsed, apparently severely injured. The intestines became tympanitic, the liver very tender to pressure, incoercible vomiting set in, thirst became intolerable, and the entire picture was one of acute peritonitis. The diagnosis had at first been penetrating abdominal wound. The patient could not have withstood an operation and death took place in five days. It appears that in some manner the shock of the bullet had activated an old appendicitis leading to gangrenous inflammation with perforation. A mere coincidence seems hardly credible. The author states that in the urgent haste of wound dressing many cases of appendicitis are clearly overlooked or as he states "slip through one's fingers." Apparently he does not refer to cases present before mobilization, but to those which appear after that period, although the present victim must represent a type of latent appendicitis without history or symptoms.

Asepsis and Amputation in War.—Schuttze has thus far performed fifty amputations, exarticulations and Gritti and Pirogoff operations. Thus far the results of asepsis have been excellent. There were no cases of erysipelas or sepsis, although several cases of tetanus developed. Healing was always smooth. The rule was to *drain*—the number of sutures had been limited to three. Iodine was used throughout. The fixed dressings demanded by the military authorities evidently had to be disregarded in a measure. The indications for amputation were comminution of the hard and soft parts, fulminating gas gangrene and shattering of the long bones with formation of necrotic pus. In more doubtful cases the soft parts were laid broadly open for exploratory purposes and incidentally for drainage. Of especial interest are the tetanus experiences. During two weeks of damp weather from 20 to 25 cases of tetanus were seen. After the weather had become dry, tetanus cases ceased entirely. The disease developed two days after a Pirogoff amputation, incubation period six days. The patient recovered under intravenous injection of serum, and morphine, Since this experience every subject for amputation receives phophylactic serum. The author implies that in all the other tetanus material the mortality is 100 per cent. Three patients still living he regards as doomed.

Intermittent Hydrosalpinx (Hydrops Tubæ Profluens).—Paul Wanner reports a case of this condition. The patient, 36 years of age, had experienced ever since her eighteenth year the periodic discharge from the vaginal orifice of a watery fluid, which was always preceded by an enlargement of the abdomen. Examination at one of these periods revealed a distention confined to the right side of the abdomen. Catheterization of the right Fallopian tube was followed by the discharge of three quarts of a limpid liquid containing no albumin. At the same time the abdominal enlargement disappeared. The cause of this condition is an atresia of the fimbriated extremity of the tube which prevents the fluid normally secreted by the latter from draining into the peritoneal cavity. If the uterine orifice is also occluded the tube may assume enormous dimensions, Schröder citing a case incorrectly diagnosed as ovarian tumor in which at autopsy the tube was found to contain nine liters of fluid.—*Revue Médicale de la Suisse Romande.*

Insurance Medicine.

Significance of Syphilis and the Wassermann Reaction for Life Insurance.—Professor Schottmüller refers to a recent article on this subject by Professor Florschütz which covers the same ground as an earlier article by himself. Florschätz refers to 167 deaths in a certain company in four years from progressive paralysis, which represent an insurance of nearly 1,800,000 marks. The author goes a little more closely into the subject. Of the 167 deaths 121 or three-fourths had been insured at ages up to 50 years. Thirty-eight of the 121 subjects had been insured for less than 5 years, 93 for less than 10 years, and but 29 had been insured for more than 15 years. Hence death followed a relatively short period of insurance. Not less fatal than syphilis of the brain is syphilis of the blood-vessels; in the author's experience no less than 40 per cent. of all cardiac cases had been syphilitic.

The author agrees with Florschütz as to the difficulty in recognizing syphilis from the personal history or results of clinical investigation. Statistics show the great frequency of the malady, especially on a basis of Wassermann testing. The author finds in this manner that 19 per cent. of men have had syphilis, while Blashko states that those who have not married before the age of 30 are infected to the amount of 20 to 25 per cent. The number who confess syphilis is but 2.7 per cent, and only 16 per cent. of autopsy syphilis was foreshadowed in the personal histories. Alienists state that only in one-third of all cases of progressive paralysis in institutions was a history of syphilis obtained. Every insurance company, in other words, has among its insured three or four times as many cases of syphilis as it has official cognizance of. In England the "supermortality" from syphilis amounts to 217 per cent.

As the author and Florschütz have already shown, all this should be avoidable by recourse to Wassermann tests. Florschütz, however, does not believe in obligatory tests, and on this course he will naturally be upheld by all those who profit from the profession of life insurance. Florschütz naturally fears perfunctoriness in testing and also the false inferences from a single Wassermann negative test in connection with syphilitic risks. These drawbacks, however genuine, seem to the author to have no serious weight against the very obvious benefits which should accrue from Wassermann selection. Ought we to bar cardiac examinations because in a certain percentage of cases bad risks secure insurance? There is a parallelism throughout between a blood test and the urine test, yet we do not abandon urine testing because now and then a nephritic subject obtains insurance.

Old forgotten syphilis in middle-aged people often escapes mention in the personal history, but such cases could be quickly checked up by a blood test. It is also a blessing to the applicant to give him a chance to be rid of this taint, whether or not he gets the insurance later. The few old syphilitics who might slip in undetected should not discredit the routine use of the blood test.

It may be objected that younger syphilitics may seek insurance when the Wassermann is in a negative phase, but this course would involve wholesale deception, such as would be readily exposed sooner or later, and threaten a disrupted claim after death.

Florschütz sees an ethical barrier to a compulsory routine test, but insurance societies are not essentially self-seeking institutions and are enlisted on the side of the greatest good to all. As the author has shown before, those rejected by blood tests benefit in the end. They have a chance to become sound and ultimately get insurance.—*Blätter für Vertrauensärzte der Lebensversicherung*, 1914, V. No. 4.

Medical Investigations.—This term covers more than one or two types as shown by Edward Magruder in his investigations on the subject with relation to life insurance. He divides the subject into five different kinds as follows: 1. Medical investigations by medical examiners, covering facts not secured at time of examining applicant. This relates to information obtained by the medical examiner from the family doctor or other interested party with reference to the applicant. It is not a neasy matter to handle as so much depends upon the skill and tact of the medical examiner. Good will undoubtedly result from special instructions of medical examiners of arguments and methods usually found serviceable in enlisting the cooperation of the attending physician. 2. Investigations by medical directors, covering the mental and moral qualifications of their local examiners. Thorough investigation, as well as appointment of medical examiners through the recommendation of the medical department, due to fitness for the position, and not through the recommendation of agents, will to a great measure relieve this difficulty of incompetent examiners. 3. Investigations by medical directors, local or special examiners, or by local examiners working under instructions from the medical directors. Especially in accident companies the nature of the accident or health risk which is accepted on the truthfulness of the statements in the original application, and without medical examination, makes a special investigation necessary. The frequency with which persons are found in possession of life policies during this contestable period, who have passed examination by the staff of the company, shows that something certainly is wrong. What is needed is a medical man who can perform the combined duties of traveling inspectors, judges of the character and present fitness of local examiners, and without any additional cost to the company, to add the benefits of their medical training to the equipment of the present salaried inspector, making his employment unnecessary. 4. Investigations by medical directors, local examiners, or both, covering the facts and circumstances surrounding the deaths of policyholders. 5. Medical investigations in their relation to cooperation between two or more interested companies. Cannot the life companies, with advantage, cooperate more closely with each other in their medical investigations and in relation to the qualifications of their examiners, also with the accident companies through their bureaus, and thus establish a service which will render better results than existing conditions now permit?—American Life Convention.

Death from Accident.—The stimulation by an accident of a dormant growth so that it rapidly results in death, which, but for the accident, would have been deferred until a later period of life, is held in Fidelity & C. Co. v. Meyer (Ark.) 44 L. R. A. (N. S.) 493, to be within the operation of a policy insuring against bodily injury, sustained through accidental means, resulting "directly, independently, and exclusively of all other causes" in death.

Book Reviews.

Appendicitis: A Plea for Immediate Operation. By Edmund Owen, F.R.C.S., D.Sc. (Hon.), Surgeon to the French Hospital; Consulting Surgeon to St. Mary's Hospital, and to the Hospital for Sick Children, Great Ormond Street, London. Cloth. Price $1.50 net. New York: William Wood & Company, 1914.

If every general practitioner who has not already seen the light as regards the necessity of immediate operative treatment in cases of acute appendicitis could be compelled to read this book, the mortality percentage in this disease would almost immediately approach zero; the deaths being practically limited to some of the occasional obscure cases in which diagnosis is unavoidably delayed, to a few of those operated upon by inexperienced men, and to the occasional complications, such as pneumonia, thrombosis, or embolism, which go to make up part of the risk attached to every major operation. Owen has stated the case fully and frankly and, we believe, justly; and we heartily commend the iteration and reiteration of the main theme—the necessity for immediate operation.

We are glad to see that he emphasizes the fact that in clear cases nothing is gained and perhaps much lost by waiting for blood counts, though their value is unquestioned in obscure cases and in certain differentiations. The chapters on Diagnosis, Differential Diagnosis, Appendicitis in Children, and Complications of Appendicitis are of especial value to the surgeon as well as to the practitioner. In this and other parts of the book the significance of deranged pulse-temperature ratio, the false sense of security that may come with the cessation of pain when gangrene supervenes, the deceptive mildness of the symptoms in some of the fulminating cases, and many other points of vital importance are strongly emphasized. All phases of the subject are covered, and that, too, with a pleasing diction that holds the attention and cannot fail to convince even the skeptic.

By way of adverse criticism we must express our utter disapproval of the author's method of closing the incision in clean cases. Silk is advised as the suture material throughout. Why not catgut for the peritoneum, muscles, and fascia, even if one should prefer some other suture material for the skin? But then, as the author says in regard to the method of dealing with the appendix, "each surgeon naturally thinks his particular way the best," and as the subject in general is so well handled, we can readily excuse what seems to us an error in technique in the operation itself; for Owen has spiked all the guns of the opposition to the proposition that acute appendicitis demands immediate operation, and that is what he set out to accomplish.

The Ileocecal Valve. By A. H. Rutherford, M.D. (Edinburgh). Price, cloth, $2.25 net. New York: Paul B. Hoeber, 1914.

The contents of this book constituted the author's thesis for the degree of M.D. at the University of Edinburgh. It consists of a critical study of the literature describing this valve, the author's observations on a living subject who had an artificial anus 8 cm. long in the cecum, the examination of this valve in two dogs immediately after death, and, finally the study of 32 specimens removed at autopsies of human subjects at periods ranging from 3 to 36 hours after death. He finds that the valve in life is quite different in many respects from the textbook description of two more or less crescentic folds or lips projecting into the cecum and having an oval or slit-like orifice. In his specimens this description would fit only those examined many hours after death, or comparatively soon after death if the temperature of the room had been fairly high, conditions evidently entailing post-mortem changes in the valve. In the fresh specimen and in the living he found the normal appearance of the valve to be "a hemispherical mammillary eminence, about 1.8 cm. in diameter, scarlet in appearance, smooth, and glistening. The summit is truncated and pierced by an orifice of a stellate appearance, with lobulated elevations between the rays of the star. This elevation is about 0.5 to 1 centimeter high. Surrounding the valve mammilla, of scarlet appearance, is the mucous membrane of the colon and cecum, which is of a pink color. No frenula are to be seen in life." He finds the valve competent, and that its function is that of a sphincter similar to the pylorus and the internal anal sphincter, and is twofold: to regulate the flow of semifluid feces through the valve and to prevent regurgitation. The work has been carefully done and his conclusions, backed up by forty or more illustrations, seem to be entirely borne out.

The Balneo-Gymnastic Treatment of Chronic Diseases of the Heart. By Prof. Theodor Schott, M.D., Bad-Nauheim, Germany. With a Foreword by James M. Anders, M.D., LL.D., Professor of Medicine, Medico-Chirurgical College, Philadelphia. Price $2.50. Philadelphia: P. Blakiston's Son & Co., 1914.

This interesting book contains a complete exposition of the Nauheim treatment of heart affection by carbonic acid baths and resistance exercises written by one of the originators of the method. This therapeutic measure has, of course, been often described by Schott and others, but never so fully and satisfactorily as in this monograph. The resistance exercises are very clearly described and are illustrated by 41 pictures showing better than words how each of them is to be executed. The book will serve as an authoritative guide to any physician wishing to acquaint himself with the Nauheim treatment, and not the least of its lessons will be, as Dr. Anders says in his graceful foreword, "a true appreciation, not only of the indications presented by individual cases for the mode of treatment in question, but also of the contraindication, so as to deter the annual exodus of 'incurables' and improper cases from making the hazardous experiment of an ill-advised expatriation."

Manual of Obstetrics. By Edward P. Davis, A.M., M.D., Professor of Obstetrics in the Jefferson Medical College, Philadelphia. With 171 Illustrations. Price $2.25. Philadelphia and London: W. B. Saunders Company, 1914.

The present volume gives in concise form a satisfactory presentation of present-day obstetrics. Although the book is small, it contains all that is really necessary on the anatomy and physiology of the mother and fetus; pregnancy, with its diagnosis, hygiene, and management; lesion, physiological, and pathological; the puerperium, with care of the infant; obstetrical operations; sections on fetal pathology and mixed feeding, and a valuable chapter on the medicolegal aspects of obstetrics. No space is wasted on theoretical discussions and academic controversies, and there are no unnecessary illustrations. We find no mention of "twilight sleep."

Rose and Carless' Manual of Surgery. For Students and Practitioners. Ninth Edition. Revised by Albert Carless, M.B., M.S. (London), F.R.C.S.; Professor of Surgery in, and Surgeon to, King's College Hospital, London; formerly Examiner in Surgery to the Universities of London, Glasgow, Manchester, Liverpool, and Leeds; Consulting Surgeon to the King Edward Memorial Hospital, Ealing; to the St. John's Hospital, Twickenham, etc. 8vo, 1420 pages, with 609 illustrations in the text and 16 full page colored plates. Price, muslin, $6.00 net; half morocco, $7.00 net. New York: William Wood & Company, 1914.

It is self-evident that a work on surgery that has reached a ninth edition and has been translated into several different languages must be one of unusual merit. "Rose and Carless' Surgery" has long enjoyed the reputation of being one of the best textbooks in the English language and is on the recommended or required list of a very large proportion of English and American medical schools. Although but three years have elapsed since the publication of the eighth edition, there have been advances of varying degrees of importance in many branches of surgery. For this reason instead of reprinting, a thoroughly revised new edition has been prepared. In this edition a chapter has been added on the use of heat, light, electricity, and radium in surgery. We are glad to see that the attitude of the author toward radium is one of sensible conservatism. He recognizes its usefulness as an adjunct to surgery, but has not been carried away by enthusiasm. Descriptions of the newer advances in the field of surgery have been incorporated in the text in various parts of the book, many new illustrations have been added as well as several new colored plates, and the work has thus been brought strictly up to date. By careful condensation and elimination the book has been kept within former space limits. The descriptions are usually models of clearness and conciseness; and it is safe to say that this edition is destined to advance still further the popularity of a work already recognized as standard throughout the world.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held January 8, 1915.

Dr. CLARENCE A. MCWILLIAMS IN THE CHAIR.

Ligation of the First Part of the Left Subclavian for Aneurysm.—Dr. V. GAUDIANI presented a man, forty-six years old, who came under his care in May, 1913. He had had luetic infection twenty years before, but had never taken any treatment. A few months before he had noticed a pulsating tumor of the size of an egg rising from the sternal notch and extending behind the sternocleidomastoid muscle. He did not show any other trouble with the exception of an area of anaesthesia on the inner side of the forearm, and a dilatation of the left pupil. A murmur could be heard over the tumor; this was also audible along the axillary vessels. Although the case had been considered an inoperable one, Dr. Gaudiani advised a central ligation of the subclavian. The operation was performed under intratracheal insufflation to prevent possible pneumothorax. An incision was made from the manubrium of the sternum, curving upward over the sternocleidomastoid muscle, and reaching down the outer extremity of the clavicle. Such an incision was decided on because it would permit eventually the resection of the sternum or clavicle and allow also a peripherial ligature in case the central was not feasible. After the muscle had been cut through, the tumor appeared covered by the internal jugular and by the upper part of the vena anonyma. The former was ligated and severed and the latter was gently pulled down. By means of blunt dissection it was possible to penetrate behind the sternum, along the carotid, until central compression of the aneurism was possible. Such compression stopped the pulsation in the sac and the radial pulse. A silk ligature was passed and a stop knot was made. The patient made a good recovery and he could now attend to his duties in iron foundry work. No radial pulse could be felt. The stretching and isolation of the subclavian loop of the sympathetic nerve, known as the ansa Vieussensi, which surrounded the sac, could explain the mydriasis of the left pupil. Dr. Gaudiani referred to the literature bearing on such unusual cases and said that only nine had been reported in Savariand's statistics (*Revue de Chirurgie*, 1906, Vol. II), which were the most recent. Of these, four were cured, three recovered, and two died. An older statistics, published by Jakobsthal (*Zeitschrift für klinische Chirurgie*, Vol. XLVIII) reported one single case of ligature of the subclavian at the same place. This case was Dr. Kammerer's and his patient died after a few weeks from secondary hemorrhage.

Dr. HERMAN A. HAUBOLD said he wished to emphasize one feature of the problem confronting them. They had before them a class of cases which presented a mortality which was high and they thought that this mortality was due largely to the method of approach. The subclavian artery laid higher in the neck than was depicted in most anatomies and, therefore, they performed an atypical operation making an atypical approach to the vessel. The operation was not a difficult one. Dr. Janeway administered intratracheal insufflation. A question arose in operating upon this patient, What would happen to the pleura? The patient, as shown by Dr. Gaudiani, was in splendid shape. He had no radial or axillary pulse and the pain and other distressing features had disappeared.

Dr. FREDERIC KAMMERER said that his case, referred to by Dr. Gaudiani, differed in some points from the one shown. The ligature in his case had to be placed around the left subclavian artery at a distance of one inch from the arch of the aorta and, in order to accomplish this, the sternal end of both clavicles and the manubrium of the sternum had to be removed. The ligature, consisting of several strands of chromic acid gut, was tightened only to such an extent that pulsation in the aneurysm ceased (MEDICAL RECORD, December 23, 1899). The patient did very well at first, the wounds healing by first intention, but he succumbed to a secondary hemorrhage four weeks after operation. At the autopsy the ligature was found apparently within the walls of the vessel, having cut through the latter.

Dr. ROBERT H. M. DAWBARN asked if the starvation plan of treatment in ligation of the subclavian for aneurysm had been tried. This method had not been tried as often as it should have been. In the work that he had done white vaseline at a temperature of 120° had been injected into the vessel and with good results. The method in conjunction with radium had a greater effect and *vice versa*.

Splenomegalic Anemia Treated by Blood Transfusion.—Dr. EDWARD W. PETERSON presented this patient, a boy four years of age with a negative family history. His trouble began when he was nine months of age, at which time it was noticed that his skin was very sallow and his abdomen was larger than it should have been. He had frequent attacks of vomiting and diarrhea with slight elevation of temperature. At the age of one and one-half years he was jaundiced. At the age of two years and ten months he was fairly well nourished and developed, but his appearance was cachectic and the mucous membranes jaundiced. The abdomen was large, the spleen extending to the line of the anterior superior spine of the left ileum, 13 c.m. below the costal margin. It was never smaller while the child was under observation. The liver extended three fingers below the costal margin. There was a gland the size of a hazelnut palpable under the angle of the left jaw, but otherwise the lymphatic system was negative. There was a systolic murmur at the apex, heard over the precordium and transmitted toward the axilla. On January 10, 1914, the blood count showed red blood cells 1,300,000, hemoglobin 15 per cent., white blood corpuscles 23,000. The differential count showed polymorphonclears, 32.5 per cent.; small lymphocytes, 31.5; large lymphocytes, 28 per cent.; transitionals, one per cent.; eosinophiles, 2 per cent.; basophiles, .5 per cent.; myelocytes, 5.5 per cent. The urine was negative save for traces of indican. The hemochrome test was also negative. The temperature was rarely normal, being usually around 100° or 101° F. Under medical treatment there was but little improvement. On May 9, 1914, the patient was sent for blood transfusion. The father acted as the donor and 275 c.c. of blood was transfused. The blood count before transfusion was red blood cells 2,530,000; hemoglobin, 36 to 40 per cent.; white blood cells, 29,000. After transfusion, the count showed red bloodcells, 4,580,000; hemoglobin, 60 per cent.; white blood cells, 14,100. Improvement followed the transfusion to such a remarkable degree that the parents considered the child well. However, in September, he again showed a muddy yellow color, began to lose weight and strength and suffered from frequent small nose bleeds. He gradually lost weight and strength until brought to the hospital four weeks ago, when he was scarcely able to stand alone. His condition was much the same as at the previous examination, except that he was weaker. As medical treatment had failed and as blood transfusion had brought about only temporary relief, and as the patient was growing progressively worse, splenectomy was advised and agreed to by the parents. On December 14, 270 c.c. of blood was transfused and this was followed immediately by splenectomy. The removal of the spleen was effected through a five and one-half inch rectus incision. The spleen weighed 422 grams. There were no attachments. The vessels in the pedicle are very large and were ligated individually. The total time of the operation was sixteen minutes. There was no shock and the loss of blood was scarcely appreciable. The wound healed primarily. The tempera-

ture of the patient ranged from 100° to 103° during the first week after the operation and then fell to normal. From the time of the operation the epistaxis stopped. This was probably also attributable to the hemostatic effect of the blood. The present condition of the patient showed an improvement as to weight and strength. The muddy color was clearing somewhat and there was no jaundice. The points of particular interest in this case were: 1. The splenomegaly with anemia commencing in infancy, the patient having no syphilis, rachitis, or malaria. 2. The marked improvement after the transfusion of May 9, 1914, followed by a recurrence of the symptoms in a more aggravated degree. 3. The very decided improvement which had followed transfusion and splenectomy. This was merely a preliminary report and the ultimate result would be given later. Dr. Peterson presented the report of the histological examination made by Dr. Sondern who diagnosed the condition as hyperplasia of the spleen and localized perisplenitis.

Arteriovenous Anastomosis for Thromboangeitis Obliterans.—Dr. C. R. L. PUTNAM presented this case. The patient was an Austrian Jew, tailor, who suffered two and a half years ago with thromboangeitis obliterans resulting in spontaneous gangrene of the big toe. This was later amputated and later an amputation in the midtarsal region was done. When he first saw him in September, 1913, he was suffering from gangrene of the stump; gangrene was on the dorsal surface of the foot, where on an area size of the palm of the hand the skin was black, dry and leathery. Swelling and edema reached to above the knee. He suffered great agony and was obliged to use codine in varying doses most of the time. At the request of Dr. Herman Appel, he did a lateral arterioveno-anastomosis, following Bernheim's technique. At the apex of Scarpa's triangle, the vessels were united and the proximal end of the vein tied off so that the artery and distal portion of the vein formed a "Y." Good pulsation in the vein occurred immediately, the valves breaking down in less than a minute. The artery wall was very thick, and its lumen correspondingly small. Immediately after the operation the circulation improved, he had no more pain and the swelling and edema of the leg disappeared rapidly. The gangrene of the foot did not recover, but a successful amputation was done above the ankle, which healed well. He has supported his large family at his regular work ever since.

When seen on January 7th, the neuritis had entirely disappeared, and since the operation he had never asked for any kind of anodyne at night.

Dr. BENJAMIN T. TILTON said that the important point in regard to arteriovenous anastomosis for thromboangeitis obliterans was the question of the permanency of the result obtained. No one doubted the fact that the blood current could be successfully diverted from the artery into the vein and that the valves of the vein were broken down by the stream of arterial blood. It was furthermore apparent in most cases of successful anastomosis that the circulation in the foot improved and the pain diminished. It was more than doubtful, however, whether this improvement continued and warded off an amputation. At the present time he had in the hospital a case of thromboangeitis obliterans who had both legs amputated for this disease. For the past year he had had signs of the same disease in one arm and hand, complete loss of the radial pulse, cyanosis, ulceration about two finger nails and severe pain. Three weeks ago he performed a lateral anastomosis between the brachial artery and the larger of the two venae comites, ligating the vein above the anastomosis. The immediate effect was striking. The pain lessened, the fingers became rosy in color and warm. This improvement, however, at the present time was not so noticeable and he doubted if they had gained any material advantage from the operation.

Dr. CHARLES GOODMAN said Dr. Putnam's case emphasized that in non-septic gangrene an arteriovenous anastomosis followed by a low amputation would prove satisfactory. All surgeons agreed that heretofore nothing short of an amputation of the thigh would relieve these cases of the excruciating pain which they were known to suffer. It was the pain above all the other symptoms which brought this class of patients to the surgeon, because it was well recognized that this symptom could not be relieved by any form of medical treatment. Arteriovenous anastomosis should not be performed in the presence of a rapidly spreading or fulminating gangrene. They did not as yet know the real cause of the disease, but an arteriovenous anastomosis would ward off an impending or threatened gangrene and prolong the life of the limb. Within the last few days he had had an opportunity of examining two of his cases operated upon respectively two and a half and two years ago. The limbs in both of these cases showed that the gangrene had been held in abeyance and amputation had not been necessary. Experience in vascular surgery, both in the laboratory as well as in the human being, led me to believe that end to end anastomosis on the vessels was preferable to the other methods, such as side to side, end to side, intubation and invagination. Arteriovenous anastomosis by this method offered the simplest technique, and while it did not cure the underlying cause of the disease, it could prolong the life of the limb almost indefinitely and relieve the patient of the distressing pain without resorting to amputation.

Dr. LEO BUERGER said that in a series of 75 amputations at least 75 per cent. would have a recurrence and have to be reamputated. The great majority of these cases would get well spontaneously, but it would require a long period of time. In fact there was no way of telling whether the patients subjected to arteriovenous anastomosis would get well or not. He asked Dr. Putnam if the veins at the time of operation delivered more blood than was expected and if they showed they were functioning properly, doing good work. He believed that one should look askance at all the results because they got as a rule but temporary improvement.

Gastroenterostomy for Duodenal Ulcer.—Dr. C. R. L. PUTNAM presented this patient. He was admitted to Lincoln Hospital in October, 1914, with diagnosis of chronic gastric or duodenal ulcer. The points of interest in this case were the extremely violent hemorrhages from which this patient suffered. He himself saw very large stools which were simply masses of blood. The attack for which he entered the hospital began five weeks before and was characterized by haematemesis and melena. Owing to his exhaustion he was kept in bed for four weeks, during which time he had less and less blood in the stools and gained considerably in strength. November 20, gastroenterostomy was done. An uneventful recovery followed and he went back to work about the fifth week.

Excision of the Pylorus for Structure Due to the Ingestion of an Acid.—Dr. PUTNAM presented this patient, who was admitted to Lincoln Hospital in October, 1914, to the medical service, with a history of having swallowed muriatic acid solution, of the strength used for cleaning stone, seven weeks before admission. He declared that before that he had had no trouble with his stomach, but was always very thin. An *x*-ray was not taken immediately because he was afraid to use bismuth in the then condition of the stomach. After two weeks of liquid diet, a small amount of bismuth was given and an *x*-ray obtained, which showed a small stricture one inch to the left of the middle line, with a fine trail of bismuth running to what looked like a stricture of the pyloric end, trailing off to tight stricture. At this time he had stopped gaining strength and was beginning to lose rapidly. The *x*-ray diagnosis was cancer, but the history of the ingestion of hydrochloric acid made it necessary to consider the possibility of traumatic stricture. At the operation the whole pyloric end of the stomach was found hard and apparently impervious. There were a few small glands in the gastro-hepatic omentum and over the pancreas, but no evidence of cancer could be found in the neighboring organs. In view of the extreme hardness of the growth, it was thought best to excise the pylorus and the cancer bearing area. This was done, a posterior gastro-enterotomy being performed. The examination of the pylorus by Dr. Rohdenburg showed no cancer but a complete destruction of the gastric mucous membrane, which was replaced by a squamous epithelium which, in his opinion, must have grown down from the esophagus. This would seem to imply complete destruction of the stomach lining. Dr. Putnam showed the specimen, the *x*-ray, and the section of the pylorus.

Etiology of Embolic Enteritis.—Dr. A. V. S. LAMBERT read this paper based on two cases presenting interesting phases both in etiology and diagnosis. He reviewed what had been reported in which the lesions were essentially the same, namely, disseminated foci of hemorrhagic infiltration of an inflammatory nature in the submucosa, the remaining coats of the intestine at first not becoming involved and the mucosa remaining intact until late in the course of the process. Dr. Lambert's cases, although they resembled these in

some particulars, presented certain differences which were of interest. The first case was that of a man, 44 years of age, who entered the hospital twenty hours after the onset of his symptoms. These consisted of pain in the hypogastric region shifting later to the umbilical region. He vomited and raised large quantities of gas. He had been constipated for several days and the abdomen was swollen. He had grown rapidly weaker and sicker and the pain had become well nigh unbearable. He gave a history of a milder attack a year and one-half before the present one. At the time of admission to the hospital the patient appeared to be *in extremis*. The man presented a condition of shock and prostration out of proportion to the physical signs in the abdomen. An acute pancreatitus seemed the most probable diagnosis, but in view of a history of stomach trouble, a peritonitis following a ruptured ulcer of the stomach was suggested. The patient appeared too ill for that condition. At operation an excess of clear fluid was found in the peritoneal cavity, which was sterile on culture and showed no pus cells or bacteria. The small intestine was greatly distended, of auniform dark color, and intensely congested. The of a uniform dark color, and intensely congested. The coils were glistening with no fibrin on them. Search was made for mesenteric thrombosis but none was found. In the mesentery, where it joined the intestine, there were fan-shaped hemorrhages, bright red in color. On the free surface of the gut there were dark hemorrhagic areas which did not appear to bear any relation to those in the mesentery. When seen from within the gut the mucous membrane was distinctly raised above the surrounding parts and appeared hemorrhagic over these areas and was everywhere intact. There was no obstruction in the bowels and distention stopped at the cecum. The appendix was not acutely inflamed. The patient survived only a short time after the operation. The operative findings were negative save for the numerous small disseminated hemorrhagic foci in the markedly distended jejunum and ilium. The microscopic examination showed findings similar to those described by Oberndorfer and Hart. While the mucosa was intact, in the submucosa there were pronounced hemorrhagic infiltrations and edema with little or no exudation of leucocytes. No emboli or thrombosed vessels could be demonstrated.

The second case was that of a woman, 38 years of age, who gave a history of abdominal pain for two days before admission to the hospital. She was not nauseated and did not vomit at first but later persistent vomiting supervened and also chills and fever. She rapidly grew weak and became prostrated. She gave no history of a previous attack. At the time of admission the case was supposed to be one of diffuse peritonitis, probably from a ruptured appendix, but the atypical appearance and the presence of profound shock threw doubt on the correctness of this view. At operation the appendix was found to be slightly swollen and congested with fibrin on the surface. Its lumen later showed the changes characteristic of chronic appendicitis. There was considerable fluid in the peritoneal cavity, the pelvis being filled with a purulent exudate. Some of the intestines were matted together with fresh fibrinous exudate, and the small intestine was covered for its entire length with flakes of fibrin and was greatly congested. The appendix was removed and drainage provided after aspirating the fluid from the peritoneal cavity. The patient died seven hours after the operation. Examination of the fluid from the peritoneal cavity showed the presence of pneumococci and diphtheria bacilli similar to those found in the lungs. These showed an early stage of broncho-pneumonia. There were a few punctate hemorrhages in the visceral pericardium. In addition there was a fatty liver, and old fibrous pleurisy and arteriosclerosis of the aorta. There were numerous small ulcers and accumulations of clots of blood bulging from the ulcers into the lumen of the intestines At the margins of these ulcers, were seen remnants of the thrombus-like mass of blood which apparently were the starting point of the lesion. Scattered through the intestine were irregular bluish masses, situated just beneath the mucosa which on section were found to be composed of clotted blood. The microsconical examination showed an intense hemorrhagic infiltration of the mucosa and submucosa with accumulation of leucocytes in many places. There was also ulceration of the mucous membrane and destruction of tissue with necrosis. Nowhere could emboli or thrombi be demonstrated. The lesions in these two cases, though they resembled those described under the term embolic enteritis, differed from them in some important particulars. They represented rather a diffusely scattered hemorrhagic infection with pronounced edema of the small intestine. The lesions began in the submucosa and rapidly infiltrated the mucosa. As the process developed there was a marked infiltration of leucocytes, and finally, in the later stages, an ulceration of the mucosa. No evidence of embolism or thrombosis could be found. The pneumococci in the second case might have been responsible for the disease, but the diphtheroid bacillus was lost and no animal experiments were made, so its exact relationship to the lesions must remain in doubt. The rarity of these lesions would lead one to the conclusion that there was some peculiar element in these cases. Might it not be possible that in pyemia the intestinal lesions were comparatively few in number in any given case and that as they formed in the submucosa and tended to rupture into the lumen of the bowel, they gave rise to small ulcers causing the diarrhea so frequent in this condition. From the standpoint of therapeutic measures, the outlook was discouraging. They were unable to remove the infected portion of the intestine giving rise to the peritonitis. It was not possible to drain the entire peritoneal cavity and operation by partial drainage would prove unavailing. None of the cases, so far as the author was aware, had been reported recovered.

Cancellous Bone Lesions.—Dr. GEORGE BARRIE presented this communication in which he reported a series of 20 cases of cancellous bone involvement that could not be classified as syphilitic, tuberculous, malignant or suppurative; neither could these cases herein reported as systemic lesions be grouped with the diseases of bone whose etiology was known to be due to disturbed metabolism through the ductless glands. The author divided this series of cases into three groups: (1) Metaplastic osteomalacia (systemic lesions). (2) Hemorrhagic osteomyelitis (local lesions). (3) Osteo-chondro-fibroma congenital tumor). After discussing the etiological and pathological theories advanced in regard to osteomalacia he concluded that further research was needed on this point. In the cases of metaplastic osteomalacia that had come under his observation all had given the physical signs of robust health. The bone lesions, except at the time of fracture, caused no symptoms of pain, tenderness, or discomfort. The cellular blood picture and hemoglobin percentage had been practically normal throughout numerous examinations. Urinary examinations had been negative for Bence Jones bodies. The Wassermann and tuberculin tests had given negative results. Antiluetic medicinal treatment had been given in two cases without apparent effect. The *x*-ray pictures had not shown any bone lesions above the pelvis in the cases observed. The routine use of the *x*-ray had been of great value in throwing light upon and demonstrating the presence of many cancellous bone lesions that only gave trivial clinical symptoms of their presence. In their work skiagraphs of the entire skeleton had been taken in all cases in which there was a suspicion of more than a single focus.

The second group of cases to which the author had given the term hemorrhagic osteomyelitis comprised those localized inflammatory processes which occurred most commonly in or near the ends of the long bones. When through operative interference the lesions were exposed, and depending upon the stage of reaction present, one of two general clearly defined forms were exhibited, namely, the hemorrhagic granulation tissue (solid) lesion or the fibro-cystic or wholly cystic lesion. The etiology was apparently primarily due to trauma. In this form of osteomyelitis the diagnosis was quite generally incorrectly made of medullary giant celled sarcoma, myeloma, medullary giant celled tumor, etc. In a paper recently published (*Annals of Surgery*, Feb., 1913, and *Surgery, Gynecology and Obstetrics*, July, 1914), the writer had discussed the place these giant scavenger cells occupied in this inflammatory process. A more active stimulant reaction with increased fibrin production caused local metaplasia and converted the hemorrhagic granulation tissue into fibrous structure with consequent retraction and cyst formation. This advanced form or stage of the initial lesion gave on operative picture of a localized fibrocystic osteomyelitis. Whether or not the lesion had advanced from the hemorrhagic to the fibrocystic, or purely cystic stage, could only be determined positively during operative interference and exposure and then only might a con-

clusive diagnosis be made. The use of the *x*-ray should always be resorted to for diagnostic purposes. At present it had its limitations. One was unable to state from the skiagraphs whether or not the more or less symmetrical lesions were hemorrhagic (solid) fibrocystic, or cystic, whether they possessed a lining membrane or did not. Sixteen cases of lesions of this group had come under the observation of the writer during the past three years. The lesions were distributed as follows: There were eight of the femur, three of the tibia, two of the fibula, and one each of the radius, ulna and ilium. Of these 16 cases, 10 had submitted to operative interference, two cases apparently would not require operation, and two others had refused operation but were being kept under observation. Two cases had been lost sight of. In the 10 cases operated upon, five proved upon exposure to be solid, that was, of the hemorrhagic non-metaplastic type; four were fibrocystic and one was frankly cystic. In only one case had the author felt it necessary to perform an amputation for this lesion. The mutilating operation in his instance was considered preferable on account of the age and enfeebled condition of the patient. In several cases the writer had been content to currette, swab the cavity with iodine and close the wound. In others where the cavities were larger partial filling had been accomplished by shavings removed from the normal bone. The ages of the patients had ranged from 3 to 63 years. The size of the lesions had varied from that of a coffee bean to a large goose egg. The relation of the size of the lesion to the duration of the disease was quite indefinite. As a rule the process was a slowly progressive one. A definite history of initial trauma was obtained in two-thirds of the cases. The period of time elapsing from the date of the injury to the onset of symptoms had varied from the time the injury had been received to eighteen months later. No lining membrane was present in nine out of 10 cases operated upon. The clinical diagnosis of these lesions in the upper end of the femur was frequently difficult to make because they simulated closely the symptom complex of hip disease of the acetabular type. The *x*-ray made a correct diagnosis easy.

In the third group of cases, those of osteo-chondrofibroma, the cancellous bone lesion must be regarded as a true tumor, that was, an autonamous growth of benign characteristics possessing the potentialities for sarcomatous degeneration. After discussing the etiology of this condition, Dr. Barrie said he had had the opportunity of personally observing only one case. This he reported on account of its rarity as a single growth in the cancellous bone and because of the interesting features it presented. The patient was a boy 12 years of age, well nourished and giving a negative family history. He had limped since he was two years of age. He gave no history of injury. He had felt no pain or tenderness in the left limb but the femur was one and one-half inches shorter than the right. An osteotomy had been performed some years ago for the purpose of straightening the bowed femur. The histological report returned stated that the condition was osteitis fibrosa. This was another instance of the mistake of making a diagnosis from an unselected portion of a diseased mass. Dr. Barrie exhibited lantern slides illustrating this case.

—Dr. Robert H. M. Dawbarn emphasized the fact that it was necessary to make a diagnosis between the ordinary malignant growths, carcinoma and sarcoma of bone, and the semimalignant ones. Other conditions such as osteomalacca, rickets or osteitis were not necessarily malignant. In osteomalacca a number of bones were involved, and this held true in rickets. In osteitis the use of the thermometer was of great value. The point he raised was that in malignant or semimalignant conditions, and long before they got any change in the shape of the bone whatsoever, the first pathological change was invariably a decalcification. This could be determined by the use of a needle held in the claws of a hemostat. If the condition was malignant or semimalignant one could pass the needle into the tumor as though it was cartilege; in ordinary healthy bone it would be found to be of stony hardness.

Dr. Wisner R. Townsend, speaking in regard to the early diagnosis of these cases, said an early diagnosis could not be made unless the patient was seen early. Many came to the orthopedist without any symptoms except swelling. Often they did not complain of pain. This was a fact that struck him in the cases brought to his observation in the hospital. Unless swelling was marked there was nothing to direct their attention to their condition until they had pain or lameness.

THE NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, Held November 4, 1914.

The President, Dr. William L. Russell, in the Chair.

Report of the Standing Committee on Legislation.—Dr. William Mabon made this report in which he called attention to the fact that the State Hospitals had failed to receive sufficient money to meet their needs and that because of this fact they were more crippled than ever before. It meant to them a serious disorganization if the present conditions were continued. The institutions depended upon a raise in the appropriation if they were to continue in doing the right work. The New York Psychiatrical Society would be called upon to designate the needs of the State hospitals. The Hospital State organization would offer every effort, as would the State Lunacy Commission, to further the work. There must be more appropriations made, or there would be a return to the conditions that existed in 1890. The working force had been reduced by about forty; the stenographic staff had been reduced; this all worked against their interest. The conditions as they existed to-day were not good and it was hoped that the members of the New York Psychiatrical Society would think over the matter and in the coming fall be prepared to help in the fight in the legislature that would enable them to get suitable appropriations for their work. Dr. Mabon stated that a bill was now before the Governor which had for its object the abolishing of the Mohansic State Hospital, and another bill which provided for the erection of a hospital instead. He believed that the members of the Society should act as a Society and not as individual members in combating this measure. The necessity for another State Hospital in the immediate vicinity of New York was imperative, as at the Manhattan State Hospital, of which Dr. Mabon was Superintendent, they care for over 4900 patients, whereas their capacity was only 3600. If this bill abolishing the Mohansic State Hospital were approved, it would be necessary to select a new site, which would result in delays and the waste of nearly half a million dollars which had already been expended for the site of the Mohansic State Hospital, and improvements thereon. The second bill provided for a site to be acquired for the sum of $25,000.00. As land within a radius of fifty miles from New York could not be obtained for a reasonable amount, it would be necessary to go further up the State, and even then land could not be had for less than $250.00 an acre. At this price only 100 acres of land would be available, whereas 1000 were required. The second bill also provided for the erection of a complete institution, including all service buildings, as laundry, store-houses, kitchens, nurses' homes, etc., at a cost of $2,000,000.00, for 2000 patients, at an average of $500.00 per capita. It was well known that at the present time a suitable hospital for this number of patients could not be erected at less than $1,000.00 per capita. He hoped that the members of the Society would write to the Governor asking him to veto both of these measures. For many years it had been his view that there should be a bond issue to provide for the new buildings made necessary by the increase in the number of insane in New York State. If such a bond issue was made, definite plans could be outlined for the next twenty years, and ample accommodations could then be provided for the excess which now overcrowds the hospitals. He had presented this question to the Legislature on various occasions during the past fifteen years but had been unsuccessful in his efforts. He was glad to see that the Governor of the State was advocating this means of caring for the insane. If this plan were in vogue they would not have so much difficulty getting suitable appropriations for maintenance each year from the Legislature. As it was now, maintenance, extraordinary repairs, and new buildings were provided for by the Legislature each year, and as the total amount was one-fifth of the revenue of the State, it had appalled the members of the Legislature and they had always reduced the amounts asked for and needed. Dr. Mabon felt that the medical profession should be behind them in what they were striving for, inasmuch as the profession was more in touch with the institutions for the insane than formerly. The profession should take them up in their efforts to raise the standard of the care of the insane; to assist them in all their studies into the causes and prevention of insanity, and in the work of the labo-

ratories. Hospital superintendents were no longer considered as hotel keepers, but as professional men engaged in the scientific study of the problems of insanity, both from the laboratory, the clinical, and the sociological aspects. They should get together before the convention met in conference with representatives of different organizations and with those who were interested in caring for the insane in order that such action as was necessary might be taken. This convention would meet early in the spring. The subject of the mental defective should also be considered. The Committee asked for suggestions from members of the Society which bore upon the work. They could make this subject a very broad one. Dr. Mabon regretted to see that mental defectives were grouped with the insane. The mental defectives composed a very large body and should receive special consideration. The State never assumed the obligation of caring for the mental defectives as it did for the insane and if the responsiblity for caring for this class could be properly placed, they would have accomplished something.

Dr. CHARLES L. DANA believed that this class should be under the charge of the State Board of Charities.

Dr. MABON said one meeting of the Society should be devoted to this subject of caring for the mental defectives for it was such an important one. By a careful study of the subject they could accomplish something, and they should begin this work at once.

Dr. THOMAS W. SALMON said that there was a tremendous interest all over the country in the care of mental defectives and in twelve different States a special study of the question was being carried on. The medical profession had not been so much interested heretofore in the study of the mental defectives as they had been in the study of the insane. It seemed particularly desirable that an Association like the New York Psychiatrical Society should go into this matter of caring for this class of people.

Dr. MABON said that there was one member of the Society who had been appointed by the Governor of the State to study and report upon this question and it occurred to him that the report he made should stand; his judgment in this matter should be of great value to the Society. Every similar society should formulate some general plan for caring for the insane, the mental defectives and epileptics. He repeated that he believed one meeting of the Society should be devoted to a general discussion of the mental defectives.

Dr. DANA moved that the report be received and placed on file and the usual course be taken. This was carried.

Committee on National Hygiene Movement. — Dr. SALMON read this report for Dr. Russell, chairman of this committee. In this report and in the discussion which followed a general survey was made of the movement, especially in Scranton, Pa., Springfield, Ill., and other cities. Surveys had been undertaken by physicians from public health committees. Many things that were being done today and not before were very impressive and more had been accomplished that had been thought possible.

A Study of Periodic Mental Depressions. — Dr. L. PIERCE CLARK presented this paper which was based upon the analysis of two cases of mild recurrent depressions of the manic-depressive type which had never sought asylum or sanatorium care. The first was that of a woman of 50 years of age who suffered from neurasthenic depressions from the time of the birth of her only child at 27 years of age. The nervous disorder occurred on a background of an open type of personality. It was shown by dream analysis and free association of the early childhood that she had an intense maternal-sister attachment, the persistent fixation of which made it impossible for the patient to adjust herself to normal sexuality or to the sequential state of maternity demanded in the marriage relations. After the birth of her only child the patient regressed to infantile trends, was depressed, and had ideas of suicide and a host of so-called neurasthenic symptoms which were symbolic of death, symptoms such as dizziness, faints, loss of breath, headache, nausea, vomiting, and a sense of impending collapse. Whenever difficult situations of new mental stress were applied the patient had a periodic depression. The analysis and therapeutic talks quickly removed the depression and the patient had found a larger and safer outlet for her interest and aims in life.

The second case was that of a young unmarried man of 34 who had an intensive love for his mother and an equally strong feeling of hate for his father. He found no adequate outlet for his aims and interest in life, had a latent and prolonged period of self-pollution, could not adjust himself to normal sexual life, and yet could not sublimate these into his life work. In alternating from these two great dilemmas of life at 23 years of age he finally undertook a line of work which utterly failed to meet the requirements of the libido in its larger sense, had a shock, regressed to the infantile strivings, became depressed, and contemplated suicide. Since the first breakdown he had had seven depressive periods at irregular intervals. The analysis was largely of the conscious life and an effort to give the patient a fair understanding of the general situation, of the precipitating causes and their relationship to the depressions. The result of analysis and therapeutic tactics was rapid relief from the depression and a much more stable and efficient outlook on life at home and in other social and business relations. The cases were presented as a contribution to the mechanism of the manic-depressive syndrome as especially elaborated by Hoch and Kirby which in its main tenets contended that after a more or less abrupt rupture of the libido the latter regresses to the infantile instincts and there when the socially adaptive tendencies of the main personality suppress or repress their strivings the person gets depressed because the libido is held back and the libido then strives for outlet in unconscious craving as shown in suicidal acts or wishes for death and union with loved ones. The author dwelt at length upon the pressing and practical importance of the scientific analysis of even the milder types of depressions and the therapeutic advantages of such procedures. It was his hope also that by so doing the baleful recurrence of such disorders might be lessened or done away with altogether.

The Clinical Varieties and Anatomical Changes in Alzheimer's Disease.—Dr. CHARLES I. LAMBERT presented this communication in which he stated that in 1906 Alzheimer had described an atypical mental disorder occurring in middle life. It was striking in the insidious development, rapidly progressive course, and the profound grade of dementia reached. Since Alzheimer's original communication some seven or eight other comparable cases had appeared in the European and American literature. During the writer's connection with the New York Psychiatrical Institute and the Manhattan State Hospital, six other cases came under his observation. The first two cases which the writer reported were both men 49 years of age without significant heredity or makeup but with a history of alcoholism. In each there developed insidiously without attacks of unconsciousness or convulsions, a most profound dementia. The onset was first evident in inattention, indifference, and absent-mindedness, later becoming more manifest in declining efficiency, progressive impairment of memory, retention, grasp, poverty of thought, followed by aimless, restless, foolish behavior, and increasing dilapidation which went on apace toward an apathetic dementia, incapacity to comprehend, to talk, to walk, and a bed-fast state in which the patient muttered, and mumbled, and fussed, and fumbled, pulled at his bedding, wet and soiled himself, chewed a little and gulped down what was put into his mouth, vegetated for a time and died like a decerebrated animal. Among the more striking symptoms in these cases were the outstanding symptoms of agnosia, aphasia, apraxia. An exact analysis of these focal symptoms presented considerable difficulty since to an impaired general recognition, word understanding, and expression, there was added a general dementia and an unresponsive, resistive attitude. At the beginning or very early there developed a conspicuous word poverty which increased to complete loss of spontaneous speech without gross paralytic symptoms developing so that one might probably conceive the aphasic symptoms resting largely on the marked dementia present and in the nature of a mixed sensory motor transcortical aphasia. In the ophosic and apraxic disorder the absence or impairment of motor function should be remarked. Dr. Lambert then related the history of a third and fourth case, the patients, being respectively 61 and 71 years of age, in which likewise there developed gradually, without cerebral irritation, apoplexy or paralytic phenomena, evidences of deterioration. In addition to the diffuse non-systemic symptoms of dementia there stood out in the first case a diffuse aphasic or paraphasic disorder, largely of a sensory type at first, later of both a sensory and motor transcortical type. There was little motor or ideatory apraxia in this case. In the second

case there was also considerable paraphasia and jargon-aphasia but more prominent were the symptoms of motor, more particularly ideatory apraxia. Here, too, must be remarked the absence of objective paralysis, although in the second case a right heminopsia was suspected, and anatomically properly so, due to a high grade parieto-occipital atrophy of the cortex of purely a senile character. The writer then related a fifth case, occurring in a woman 56 years of age. The case was admittedly impure clinically. There was moderate alcoholism, probably insufficient to produce or account for the Korsakoff-like syndrome. There was no history of trauma but such could not be wholly excluded as a thin rust colored membrane lined the dura; however, the gross appearance of the dura was everywhere intact and healthy looking. The more probable condition was a premature presbyophrenic complex. However, the distribution and character of the anatomical changes were of special interest in relation to such a possibility. The influence of all the factors enumerated, however, could not be denied. In nearly all the cases the onset at an early age would seem to preclude a simple senile dementia from consideration. The rapid course and grave dementia with the appearance of aphasic and agnosic symptoms, and some ataxia, might suggest a brain tumor, but pressure symptoms were absent. An arteriosclerotic brain disease could be excluded because of the absence of peripheral arteriosclerosis and development of a deep dementia without antecedent history of headache, vertigo, or apoplectic attacks. A typical general paralysis might have been considered most probable but the biological finding should control this. An atypical Lissauer type of general paralysis might be thought of in all the cases, but especially in the third and fourth. Traumatic insanity might be considered but in one case only was there such a possibility. Alcoholism might have played a minor rôle but the essential features of chronic alcoholism were lacking. The symptoms indicated a wide spread severe cortical disease, in type comparable to a grave senile dementia, premature in development and more profound in degree. The pathological process underlying this condition had not been fully and accurately studied. It appeared to develop irrespective of vascular fields and the normal condition of the vessels inclined one to believe that some form of abiotrophy underlay the disease process predisposing the brain to earlier senile involution. In both cases presented, in the atrophic field the plaques were not only more numerous but the fibrillar changes more severe, the nerve cell loss more pronounced, and neuralgia reaction more marked than elsewhere in the brain. The prototype of this disorder was probably represented in the Lissauer types of general paralysis. Again the clinical pictures presented by these groups of cases were essentially different from the presbyophrenic complex not infrequently occurring in senile dementia. While attempting to perceive the distinctions between the individual cases and grouns of cases here presented, the writer said he was fully aware of the fundamental continuity of the pathological process in all of the cases. The writer by means of lantern slides demonstrated the anatomical changes present in the several cases present.

Dr. H. A. COTTON said that these cases of Alzheimer's disease were not very numerous. He had one case under observation which he believed to be a case of this disease. For a long time there had been a partial general paralysis although an examination of the cells in the spinal fluid proved negative. Clinically this was a typical case of the kind described by Dr. Lambert. The anatomical findings were interesting in relation to the fat, to the relation of neuroglia, and the getting rid of the fat to the blood vessels. An important fact suggested by the reader of the paper was that metaholic changes did take place in the cortex. He thought that the more familiar they became with such cases, the more cases of Alzheimer's disease would be found and especially when they came to autopsy. He had seen but one case.

Dr. GRAEME M. HAMMOND said he had been particularly impressed with the paper. Personally he had never made a diagnosis of Alzheimer's disease and he thought it was possibly due to the fact that he knew so little about it. They probably saw these cases oftener than they knew, but as yet they were not able to differentiate them from paresis or dementia. From a study of the clinical features they would be better able in the future to make a diagnosis.

Dr. AUGUST HOCH said he had seen one case that clinically was Alzheimer's disease and one that Dr. Lambert also had seen. The case he saw he thought might have been of that sort. There was a dementia occurring in a relatively young man. He showed a previous organic dementia with diffuse aphasic disorders in general suggestive of a previous deterioration. There was a general paralysis but no arteriosclerosis.

Dr. SWEPSON J. BROOKS said he hoped that some day Dr. Lambert would report on a study of cases that were rarely mentioned, that was, cases of precox, showing that the same conditions were responsible for the symptoms presented. He felt that these cases were not explored sufficiently. There were certain substances in the body, toxic in nature, which were responsible for the condition. Dr. Lambert had shown that there was no condition of the arteries that was responsible for the breaking down of the cells; this was shown in the slides. Dr. Lambert had pointed out a field that should be productive of very interesting work.

Dr. H. A. COTTON asked Dr. Lambert if there were any convulsions in the case he reported.

Dr. LAMBERT replied that there were no convulsions in any case.

Dr. H. A. COTTON said that there was a patient who had been in the hospital five years and during the last month or two he had had two typical paretic convulsions.

Dr. LAMBERT said that they should suspect such cases as being of cortical nature. With regard to the fat content in the plaque it was not known whether it represented local tissue degeneration or degeneration of certain products deposited in the plaque. It was suggested that possibly degeneration exceeded local elimination and precipitation probably occurred.

The Differential Leucocyte Count.—S. R. Miller concludes that the total leucocyte count and differential formula in normal individuals are subject to relatively wide variations, which must be considered in the interpretation of studies made upon the blood of individuals presumably suffering from abnormal conditions. The interpretation of any differential count should be based upon a knowledge of that particular individual's normal blood picture, when possible; the average values for the locality in which that individual resides, and a consideration of those factors peculiar to the individual which might modify that particular blood. Differential leucocyte counts should always be reported in terms both of percentage and absolute numbers per cubic millimeter, and in all cases, where possible, more than one differential count should be made, especially in borderline cases in which slight changes are to be regarded as of diagnostic or prognostic value. The tendency to ascribe a diagnostic value to lymphocystosis is probably overdone. Only when the mononuclear elements constantly exceed the average percentage, the absolute values, and the upper limits of variation (35-40 per cent.) for the community, and when all modifying factors are considered, Miller claims, should one attempt to draw important and valuable conclusions from the figures obtained.—*Johns Hopkins Hospital Bulletin.*

Autoserotherapy in Dermatology.—José S. Hilario finds that autoserum alone is capable of producing spontaneous involution of certain dermatoses, especially those of actinic and nervous origin, and of those which have proved rebellious to chemical medication. As an antipruritic agent, autoserum is an excellent remedy. It plays a very active influence in the treatment of psoriasis in reducing the resistance of psoriatic tissue, thereby rendering it more apt to be acted upon by chrysarobin in weak percentages. Two or three per cent. chrysarobin is enough to produce a complete desquamation of the epithelium involved in the areas of psoriasis, in combination with the autoserum treatment. Owing to the low percentage of chrysarobin necessary to bring about healing, the possibility of producing secondary dermatitis, in psoriatic patients, is practically ruled out. While the autoserum, when it is aseptically and properly prepared, gives rise to no clinical reaction, it is capable of augmenting the hemolytic amboceptor in the serum from the individual into whom it is injected. The use of chrysarobin is not necessarily to follow a determined number of injections. The earlier the application of the ointment the faster the healing of the disease.—*Journal of Cutaneous Diseases.*

THE MENTALLY DEFECTIVE AS CASES IN THE COURTS OF NEW YORK CITY.

BY MAX G. SCHLAPP, M.D.,
NEW YORK CITY.
DIRECTOR OF THE CLEARING HOUSE FOR MENTAL DEFECTIVES, PROFESSOR OF NEUROPATHOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL,
AND
LETA STETTER HOLLINGWORTH, M.A.,
NEW YORK CITY.
PSYCHOLOGIST IN THE CLEARING HOUSE FOR MENTAL DEFECTIVES.

(From the Clinic of Prof. Schlapp.)

IN recent years there has been a growing tendency among the more intelligent workers in penal institutions and in departments of correction, which may briefly be characterized in the idea that "the criminal, not the crime, should be punished." This tendency is indicated by the many studies of inmates of reformatories and prisons which have recently been made and are now in progress. No attempt will be made here to review the literature that has appeared on this subject. The writings of Saleilles on "The Individualization of Punishment" and of Grasset on "The Semi-Responsible and the Semi-Insane" present general discussions of this idea, and have no doubt stimulated experimental work. Interesting investigations are being carried on at Bedford Reformatory, among the juvenile delinquents in Chicago, and in various other places. The present paper deals with but one group of delinquents, *i.e.* the mentally deficient, and comprises a careful statistical analysis of 520 cases from the courts of New York City, examined during the past 21 months in the Clearing House for Mental Defectives.

The general organization and procedure of the Clearing House for Mental Defectives have been recently described by the present authors[1,2] and will not be rehearsed here. Among the 5,700 cases examined at this clinic in the 21 months since its establishment were 520 court cases. Each of these cases was given a mental, physical, and social examination, and the more important results of these examinations are presented here in the form of a statistical analysis. There has been an attempt to answer some of the questions that occur most naturally to the examiner, for example:

1—What charges are brought in the courts against those delinquents who are found to be mentally deficient?

2—Is there any correspondence to be discerned between the degree of deficiency and the nature of the delinquency?

3—How are the delinquents distributed as to age, both actual and mental?

4—To what extent are the delinquents physically defective?

5—How are mentally defective juvenile delinquents distributed in the schools?

6—What significant facts are revealed in the family histories of these patients?

7—What recommendations are made by experts for the final disposition of the offenders after the examinations have all been completed?

It should be understood at the outset that this study does not pretend to teach anything concerning delinquency in general. Also it tells nothing as to the percentage of feeble-minded individuals among court cases. It touches only upon offenders who were suspected, by magistrates or probation officers, of being mentally abnormal. The cases came from the various Courts as follows. The vast majority were brought from the Children's Courts, for the reason that the Director of the Clearing House happens also to be the official examiner to the Children's Court.

TABLE I—COURTS FROM WHICH RECEIVED (1913 AND 1914).

Raymond St. Jail	1
Harlem Court	1
Dept. of Correction	1
N. Y. District Attorney	1
City Prison	1
Total	520

Distribution of the Basis of Age.—Table II shows that comparatively few individuals in our group are below ten years of age actually. The greatest number of juvenile cases appears at the Clearing House between the ages of 13 and 15 years—that is, at adolescence. A similar situation is shown in figures recently published from the Psychopathic Institute in Chicago by Dr. Augusta Bronner.[3] Twenty-five of our adolescent cases were found after examination to be of normal intelligence and were diagnosed as mentally unstable. This condition, appearing characteristically at adolescence, and accompanying the somatic changes which take place at that time, may be transitory and recoverable, or it may be the first outcropping of a fundamental neurotic weakness, which will affect the individual throughout life. Even with the imbeciles and morons it is often the case that unstable and criminal tendencies first manifest themselves at the beginning of adolescence. The following cases may serve to illustrate this point:

4353.—Girl. Actual age, 14 years; Binet age, 10 years; school grade, 7A. Arrested while wandering about the street at night. "Since she turned 12 years old she has been very disobedient, uses vile language, etc. About two months ago she took money from her mother's pocketbook. The patient became angry at the mother's scolding, and left home. About 6 o'clock the police brought her in, saying they had found her in Long Island City. She told the police she had been kidnapped. * * * Whether the retardation on the

Binet is due to actual mental deficiency or to temporary instability * * * is difficult to say. Further observation is necessary."

4222.—Boy. Actual age, 14 years; above the Binet. Left school from class 7A. Arrested for associating with vile and vicious persons. "Patient is certainly not mentally deficient. For the past two years, *i.e.* from the time when he was about 12 (the period of pubic stress) his conduct has been unsatisfactory. * * * Is impulsive, and states that he would not be sure of himself if he promised not to run away again."

3763.—Boy. Actual age, 12 years; Binet age, 10.2 years; school grade, 5A. Arrested on complaint of mother for incorrigibility. "The boy presents a fairly normal mental condition, although he is very emotional and easily upset. * * * If he does not improve, it is advised that he be placed somewhere so that he can be guarded against the temptations of his present environment. The condition is unquestionably due to adolescence."

3277.—Girl. Actual age, 12 years; Binet age, 9.6 years; school grade, 4B. Patient "holds up" children on the street and takes money from them. "Mother states that up to one year ago patient was a good girl, and never did anything wrong. Mother cannot account for the change in her actions. Last week patient played truant from school. She meets her brothers on the street, and induces them to play truant with her. She has become unruly and wild of late, and when corrected flies into a passion."

Table II—Showing Distribution of Delinquents Under Actual Ages and Binet Ages.*

Actual Age	Binet Age										
	Below 3	3	4	5	6	7	8	9	10	11	Above Binet
5			1								
6	2				1						
7			1	1	2	2					
8				3	2	8	1	3			
9			1	1	6	4	7	7	3		
10			1		5	7	10	6	7		
11			1		4	1	11	6	11	6	
12		1	3	2	1	6	5	13	12	7	2
13				1	2	7	4	17	18	8	1
14			1	1	5	7	6	11	23	14	7
15				2	5	5	16	32	26	20	19
16					1		1	8	3	9	4
17						1	2	5	3	1	1
18						3	2	1	1	2	
19								4	2		
20							1		1		
21		1		1		1		3	2	1	
Over 21	1		1		1	3	1		1		1

*Fractions are dropped when less than .5, and counted as a whole when more than .5. All records above 11.4 years on the Binet Scale, are rated as "Above the Binet."

Diagnosis.—The diagnosis of these cases ran as follows: In the table diagnoses are given without details of etiology, etc., which are given in the histories. For example, "retardation due to environment," "retardation due to epilepsy," "retardation due to physical cause," etc., are all given in this table simply as "retarded."

Table III—Summary of Diagnoses.

Morons	87
Imbeciles	84
Retarded	66
Mentally defective (degree as yet undetermined)	50
Mentally and morally defective	23
Neurotic	36
Moral imbeciles	36
Normal	28
Mentally unstable	25
Moral deviates (N. F. M.)	29
Epilepsy	5
Dementia praecox	6
Environment	10
Idiots	3
Not feeble-minded, but eccentric	1
Alexia and agraphia	1
Alcoholic dementia	1
Wanderlust	2
Chorea	1
Neurasthenia	1
Hysteria	1

Nature of the Delinquencies.—The various crimes and misdemeanors of which the patients had been accused are distributed as follows:

Table IV—Summary of Charges (1913 and 1914).

Theft and accomplice in burglary	131
Truancy	63
Sexual misbehavior	54
Improper guardianship or no guardianship	48
Incorrigibility (no specific charge but many general complaints)	45
Disorderly conduct (cursing, throwing stones, etc.)	33
Fighting and assault	22
Truancy and stealing (double charge)	20
Associating with vile and vicious persons	12
Witness or victim in white slave case	8
Murder and attempted murder	8
Vagrancy	6
Intoxication	6
Lost child	6
Arson	6
Begging	5
Peddling without a license	5
Broke parole	4
Attempted suicide	4
Carrying concealed weapons	3
Stabbing children and putting out their eyes	3
Waif and homeless	3
Corrupting the morals of children	2
Witnesses in felony cases	2
Destroying property	2
Forgery	2
Father tried to force schools to take child	1
Cruelty	1
Gave self up to police	1
Charged with being an improper guardian	1
Taking and procuring drugs	1
Intolerable nuisance	1
Violating child labor laws	1
Abandoned her child	1
Obstructing public entrances	1
Unlawful entry	1
No charge ascertained	1

It will be seen that theft and accomplice in burglary and truancy are the most frequent forms of delinquency. The adolescents, who are greatly in the majority among our cases, were classified in five groups with respect to mental age, and their crimes and misdemeanors were then tabulated in order to discover whether such an analysis would reveal any correspondence between degree of deficiency and the nature of the delinquency. Individuals from 12 to 16 years of age were included and were grouped as follows:

1—At age and above, the Binet scale.
2—Ten to twelve years, mental age.
3—Nine to ten years, mental age.
4—Eight to nine years, mental age.
5—Below eight years, mental age.

Practically every charge noted in the total list of charges occurred in every group, but there was a notable difference in the relative frequency with which the various types of crime and misdemeanor appeared under these five mental ages. In the first group, including those at age or above the Binet scale, those offenses occurred most frequently which require a certain amount of personal initiative for their accomplishment—assault, grand larceny, attempted burglary, attempted suicide, and sexual offenses of an aggressive kind. In the second group, comprising those who showed a mental age of from ten to twelve years, much the same charges were found as in the first group, except that truancy, arson, and disorderly conduct occurred with greater frequency. In these two higher groups such charges as improper guardianship, lost child, and vagrancy occurred with comparative infrequency. In the third group, including those from nine to ten years of age, mentally, the most frequent charges were sexual misbehavior, truancy, and theft. A very large percentage of the girls falls into this group and these are the most frequent charges brought against them. In the fourth group, comprising those eight to nine years old, mentally, charges of improper guardianship, truancy, associating with vile and vicious persons, and petty larceny, increase in number. Immoral conduct of an unaggressive kind is often charged. This is true also for the fifth group, which contains those under eight years of age, mentally, where charges

of improper guardianship, vagrancy, truancy, lost child, peddling without a license, and general incorrigibility predominate. These are, of course, the offenses which have their source in a general tendency to drift about, and a failure to perceive the social environment. They arise from a total lack of personal initiative, and are quite different from those noted in the highest group, where a certain amount of aggressiveness is necessary. However, it is not to be inferred that the lower grade of defectives includes only so-called "harmless" individuals, for occasionally a very vicious crime is reported among them. The general result of this analysis is about what might be expected, *a priori*, to eventuate.

Practically all offenses included in the general list were committed by members of both sexes. No crime which occurs with any considerable frequency is charged to one sex alone. Theft, truancy, sexual misbehavior, improper guardianship, incorrigibility, disorderly conduct, assault, etc., were charged to both boys and girls. But there is considerable difference in the relative frequency with which these various offenses are charged to the sexes. The following table gives the percentage of the total number of each sex charged with the various offenses. The total number of males examined was 371; the total number of females, 149.

Offense	Theft	Truancy	Sexual Misbehavior	Improper Guardian	Incorrigibility	Disorderly Conduct	Assault
Male	28.0%	15.1%	3.2%	7.3%	14.0%	4.8%	5.3%
Female	8.7%	10.1%	28.8%	15.4%	7.4%	4.7%	2.0%

The proportion of females arrested for sexual offenses is nine times as great as that of males, but for assault the proportion of females is only half as great as that of males. For improper guardianship females are arrested, in proportion to their total number, twice as often as males, but only one-third as often as males for theft. The sexes are arrested in equal proportion for disorderly conduct, but males are proportionately arrested twice as often as females for general incorrigibility.

It is impossible to say how much of this difference is due to original nature and how much to the difference in social attitude and environment to which the sexes are subject from birth. It is extremely unlikely, for instance, that girls are proportionately nine times as prone to commit sexual offenses as boys are. It is much more reasonable to suppose that, since sexual misbehavior is followed by such different results in the case of the two sexes, it is regarded by parents and society at large as a much more serious offense in the case of females, and that therefore girls are much more likely to be arrested for this offense than boys, though the latter may actually be more prone to it than the former. The results further suggest that sexual offense, on the part of girls, is more likely to be interpreted by parents, probation officers, and others as indicative of mental weakness than when committed by boys, and that girls are more likely to be brought, not only to the courts, but to the Clearing House as well, on this account. In the matter of theft, likewise, the fact that, proportionately, three times as many boys as girls are arrested on this charge, is probably no indication that boys have any greater innate tendencies to peculation than have girls. Boys are allowed to run about the streets, as girls are not, and thus form gangs and have much greater incentive and opportunity to steal than have girls.

In the course of a study such as this a certain amount of insight is gained into the social phenomenon known as the "gang." These gangs, formed among young boys, often persist as social entities after the members have reached maturity. The following extracts from histories will illustrate the relation which exists between juvenile delinquency and the "gang."

Case 2980.—Actual age, 15 years. Binet age, 8 years. Diagnosis, imbecile. Taken by father to the Children's Court, charged with incorrigibility. "He says he spends his time playing ball and shooting craps for buttons. He belongs to the 'Glendale Gang,' and he says the object of this gang is to fight each other, stealing, gambling, and ringing fire alarm boxes to see the engines run; although the boy claims he does not do these things himself."

Case 2675.—Actual age, 11.5 years. Binet age, 11.2 years. Diagnosis, intellectually normal but neurotic. Charged in the Children's Court with destroying property. "Probation officer's best methods failed to get him to tell of his offense. Inquiries made outside determine that he is not only a member of a gang that habitually commits the offenses charged, but that he is their leader."

Case 3615.—Actual age, 14 years. Binet age, 8.6 years. Diagnosis, deferred. Arraigned in the Children's Court for shooting a boy. "Dr. Schlapp questioned this boy, and he stated that he is a member of a gang by the name of 'East River Boys,' and that this gang 'has it in for' 'The Black Caps.' He was asked whether he would hesitate to shoot a man, and he seems to think it would be perfectly natural for him to do so, and this is the right way to look at matters. The boy must return for further observation."

Case 3818.—Actual age, 12 years. Binet age, 11 years. Diagnosis, mental instability, due to adolescence. Arraigned in the Children's Court for breaking parole. "He has been irritable and cranky for about one year. * * * He has been going with a gang, and this gang of small boys is frequently used by larger boys who induce them to steal, etc."

Case 4501.—Actual age, 14 years. Binet age, 7.2 years. Diagnosis, mentally deficient. Arraigned in the Children's Court for theft. "Officer saw a Mrs. S. —— who keeps a grocery store. She states boy is wild and hangs out with toughs, and that he goes with a gang who annoy her and her husband." A letter from the Department of Education further states, "We have known him for many years as a gangster and a truant."

Case 4559.—Actual age, 14 years. Binet age, 7.4 years. Diagnosis, imbecile. Arraigned in the Children's Court for theft. Belongs to the same gang as No. 4501. Both of these boys are in school in the ungraded classes.

Case 3571.—Actual age, 9 years. Binet age, 6 years. Diagnosis, high grade imbecile. Arraigned in the Children's Court for theft. "He was with a gang of boys who had taken a gown hanging in front of a store. Two of them were caught, the patient being one of these."

Recommendations for Disposition of Cases.—The recommendations of the examining physicians in regard to the final disposition of the 520 delinquents are interesting, especially in the contrast they afford to the former disposition of such cases. Formerly the majority would have been sentenced to penal institutions or to other forms of punishment. After examination by experts in pyschiatry it is noticed that only two out of 520 were recommended for penal institutions. Fifty-eight per cent. of the entire number were deemed fit subjects for detention in institutions for the feeble-minded or for clinic treatment. Philanthropy or "uplift work" in the ordinary sense was thought by these experts to be indicated in only six cases of the 520, whereas, as a matter of fact, a great amount of time, effort and money had already been spent in futile attempts to rehabilitate and to reform the

mentally defective persons included in the number. If social workers and the agents of philanthropic organizations in general could be trained to recognize the more obvious indications of mental abnormality, much time and money, at present wasted, might be saved. Punishment prescribed by law and moral suasion have little deterrent effect on this class of delinquents. Most of them do not appreciate the difference between right and wrong and have no perception of the social customs and expediencies which regulate the lives of those about them.

On the other hand, a certain percentage of those suspected of being mentally defective are found upon examination by experts to be intellectually normal, but to be suffering from remediable ills, social or physical. Such cases may be afflicted, for instance, with some toxic condition, with some nervous disorder, such as chorea, with temperamental difficulties, with anaemia or malnutrition. Or they may be the victims of a strange or vicious environment. Occasionally, for instance, it happens that an alien child is brought to the clinic, whose actions have led to the suspicion that he may be mentally deficient. Sometimes these newly landed aliens are found, upon examination, to be of normal ability intellectually, but as yet unadjusted to the new and strange environment. In these cases the individuals may be saved from anti-social careers by timely remedies wisely applied.

The following table (Table VI) gives the various recommendations concerning the cases. In some instances no intelligent recommendation for disposal could be made, owing to some technicality or circumstance connected with the case, or to the lack of a proper institution in which to detain the patient. This latter condition was especially true of the moral imbeciles. There is no institution in the State to which these cases may properly be sent. Many of them cannot be included in the category of the mentally deficient, hence cannot be sent to institutions for the feeble-minded, and they have no proper place in reformatories, since their defect is congenital and incorrigible. Yet they constitute, if anything, a greater menace to themselves and the community than do those who are defective in the strictly intellectual abilities.

TABLE VI.—RECOMMENDATIONS FOR DISPOSITION (1913 AND 1914)

Institutions for the feeble-minded	205
Clinic treatment	100
Change of environment	36
Strict supervision and discipline	34
Further observation	28
Institutions other than for feeble-minded	23
Physical treatment	16
Probation	9
Charitable aid, social-endeavor	3
Big Brothers	3
Deportation	2
Penal institutions	2
School	1
No recommendation possible	58
Total	520

There is, moreover, urgent need of State institutions for the criminally inclined who are at the same time definitely mentally deficient, for it is not socially just to commit the feeble-minded who are not delinquent to the same institutions where delinquents are detained. It seems likely that the State Commission at present working upon this general problem will recommend the establishment of separate institutions for male and female delinquents who are feeble-minded, so that these may be segregated from those who are mentally defective, but morally harmless. The intelligent cooperation of judges and probation officers is doing more and more to bring the delinquent feeble-minded to the attention of the expert, but State provision must be made for the proper disposal of these cases, or all the effort of judge, probation officer and expert psychiatrist fails of its whole purpose.

Heredity.—Twenty-eight per cent. of the cases showed bad family histories. These figures are undoubtedly too small, because in many cases it is practically impossible to obtain any family history at all, and in the majority of cases it is impossible to go beyond the grand-parents in obtaining facts. It is obvious that a trustworthy statement regarding heredity should be based on nothing less than an examination of all the closely related individuals, exactly the same as that to which the patient himself is subjected. Statements by parents and other members of the family regarding the amount of insanity, criminality, feeble-mindedness, etc., among relatives will probably almost never tally with the results of expert examinations. This desirable procedure would have been impossible in most cases, even had the funds and the facilities for the work been available, for these patients were, in a large percentage of cases, immigrants or the children of immigrants, with most of their relatives in Europe. When criminality, insanity, excessive alcoholism, epilepsy or feeble-mindedness is both recognized and acknowledged by the inexpert, and often grossly ignorant, persons giving the history, it is almost certain to have been actually present in a very marked degree, and, as stated, in 28 per cent. of these cases the presence of such factors was reported. These results, to be significant, should be checked up by family histories of a similar number of individuals taken at random in the community. The facts cannot be properly interpreted as they stand, and are only given here as being of more or less incidental interest.

Distribution of Juvenile Delinquents in the Schools.—Sixty-eight per cent. of the delinquents examined were attending school at the time of their arrest, either in the public schools or the parochial schools. They were distributed through the school grades as follows:

Grade	Kindergarten	First Grade	Second Grade	Third Grade	Fourth Grade	Fifth Grade	Sixth Grade	Seventh Grade	Eighth Grade	High School	Ungraded or Special Classes
Number attending	1	21	38	69	54	62	36	8	5	2	56

Since but 28 of the total 520 cases were diagnosed as normal, it follows that practically all of these delinquents in the schools were afflicted with some form of mental abnormality. The mode for the group falls in the third grade, whereas the modal age of the group is fifteen years. The modal school status of average children fifteen years of age is in the high school. According to this table teachers may expect to find mentally abnormal juvenile delinquents in any school grade, but they are to be expected most often from the third to the fifth grades. For a complexity of reasons they seem to accumulate at this point in school progress. Comparatively few of them can get beyond the fifth school grade, but a great many of them can reach the third grade, where average children of eight or nine years are found.

Of these children in the schools, 48 per cent. were found definitely feeble-minded, and were distributed as follows:

Grade	First Grade	Second Grade	Third Grade	Fourth Grade	Fifth Grade	Sixth Grade	Ungraded
Number attending	10	19	35	23	22	14	48

The great majority of the children had physical defects or symptoms of disease. These ranged all the way from carious teeth to serious conditions like syphilis and grave heart lesions. Some of the conditions were remediable by operation or medication, and the patients showed notable mental improvement after treatment, in cases where the mental condition was one of "retardation."

Conclusions.—The facts observed here have certain implications which should be of interest to the public at large, and especially to those who are concerned with courts, penal institutions, reformatories, or any other phase of social rehabilitation. A large number of delinquents are undoubtedly mentally irresponsible and in considering any particular case mental abnormality should occur as a possible causative factor. The only way to tell how many of the persons who pass through the courts are mentally abnormal would be to examine every one of them. At present only those are apprehended who are so obviously and flagrantly defective as to arouse the suspicion of persons inexpert in psychiatry. Many of the individuals finally brought to the Clearing House and diagnosed as imbeciles or morons were "repeaters," with records of five or six appearances in court. Totally irresponsible and hopelessly incorrigible, they had simply drifted from one term of punishment or from one period of probation to another, unrecognized as mentally defective. A case in point is that of a girl of sixteen years, a domestic, who had drifted from one place to another, discharged again and again, for petty offenses, until at length she committed a serious theft and was brought to court. It occurred at last to one of the workers in the shelter to which she was sent, "that there might be something wrong with her mind." She was brought to the Clearing House where she was recognized after examination as a high grade imbecile. All the philanthropic efforts that had been spent on her were absolutely wasted, for the girl was and always will be without insight into social situations. The penalty prescribed by law for the offense which she had committed was in reality irrelevant to her case. She could not be reformed, since she had not the power even to perceive the laws which she had broken, and there could be no social gain in sentencing her to a penal institution, since she was neither in any true sense responsible for her deeds nor able to profit by punishment.

Also in the case of those adolescents who suffer from mental instability, as described above, reformatories and penal institutions are not indicated. The outlook for these individuals is good if they can be placed in a favorable environment under wise supervision until the period of adolescence is past.

To those who have worked over the mass of material connected with these cases, and who realize what a small percentage of the total number of cases that pass through the courts yearly is here represented, it is clear that the great problem of individualizing punishment has as yet scarcely been even attacked. For many reasons it seems that the Children's Courts afford the best point of departure for the working out of a general scheme for social betterment in respect to the problem of delinquency. If every delinquent child could be thoroughly examined, mentally, physically, and socially, on his first appearance in the court, and disposed of according to the results of such examination, a great gain would without doubt be made towards the solution of the problem of adult delinquency. Several of the adult prisoners examined at the Clearing House had made their appearance in the Children's Courts while they were under sixteen years of age. If these defectives could have been properly apprehended at that time, their subsequent crimes could have been spared to themselves and to the community.

However, as has been mentioned before, much progress has been made in recent years in realizing the fact that a problem exists. It seems well nigh incredible now that only fifteen years ago there was no Children's Court in New York City; that children were tried and sentenced like adults. Mental and physical examination was unthought of. It was indeed the crime, and not the criminal, that was punished.

Recent investigations among inmates of various penal and reformatory institutions have revealed the following facts.

The New York Reformatory at Elmira finds 37 per cent. of its inmates clearly feeble-minded; the New Jersey reformatory at Rahway, 33 per cent.; the New York Reformatory for Women, at Bedford, 37 per cent.; the Massachusetts Industrial School for Girls, at Lancaster, 50 per cent., and the Maryland Industrial School for Girls, at Baltimore, 60 per cent.

These figures, since their publication last year, have become familiar to workers in the general field and need not be further commented upon at this time. There is no doubt that the results of special investigation must in time accumulate to such an extent that society at large will become aware of them. And this growth of knowledge will eventuate in a system of correction and justice under which there will no longer be any attempt to punish the irresponsible or to reform the feeble-minded.

AESCHYLUS—A DOCTOR'S STUDY.

BY W. B. KONKLE, M.D.,

MONTOURSVILLE, PA.

To know what is needful, that is wisdom; not to know much.—(Aeschylus cited by Stobaeus.)

AESCHYLUS, the thunderous, Mrs. Barrett-Browning designates him. In their intensity, their grandeur, their sublimity, their inspiration of awe, his lines move and resound like the lines of the great Hebrew prophets who from some one to three centuries went before him. Is not Greek culture in full flower the finest, the most lustrous product of mind's conquering and creative reign? Truly Greece at her zenith is the crown of historic time. The golden age of Hellas is the golden age of the world. Oh! the might and light of thought and spirit concentered and condensed in that brief

epoch! Of "the glory that was Greece" Aeschylus is an integral and noble part. Than he no star vaster, none more resplendent, shines in that rarest and fairest of constellations which Hellenic genius set in duration's firmament.

Aeschylus is by general acclaim styled the Father of tragic drama; just as Herodotus is known as the Father of history, and Hippocrates, the Father of medicine. But as there was history before Herodotus, and medicine before Hippocrates, so was there tragedy before Aeschylus. What these pioneers, recognized as such, *did* do, however, and what entitles them to primacy in their respective fields of effort, is to have garbled and classified and clarified, and thus put in available form the whole mass of accumulated opinions, ideas, and lore appertaining to mankind as a common heritage. The Greeks were, indeed, marvellous creators besides. But they are, nevertheless, notable as extractors of cream from cisterns of milk drawn laboriously by other men of all times and all climes.

Our further sketch will aim to present that interest in Aeschylus which might be deemed more peculiarly to concern the doctor. Studying our author from this viewpoint we may notice first his allusions to medical fable. Though not numerous these are well chosen and distinctly outlined. In his interpretation of the grand Promethean myth Aeschylus narrates how the unconquerable fire-giver taught and trained the sluggish, stupid, helpless human race, leading and lifting it to a plane of conscious and confident power. Does not his stately rhetoric roll down the "corridors of time" like Darwin in epic metaphor? From "Prometheus Bound" are taken these passages: "Thou knewest not how little it could do, this inertia, true paralysis of nightmare, which enchained the children of this idiot race?" "Did one fall ill, no relief at all, neither nourishment, nor ointment, nor drink. For lack of medicine the sick one died until I had shown the salutary preparations which to-day cure all maladies." Aeschylus does not fail to pay homage to Apollo, the healer. In "The Eumenides" he hails him as "all-powerful Loxias," adding that "he is the god of medicine" and "the purifier of others' houses." In the same drama he apostrophizes the divine physician, as savior of Admetus, thus: "Thou wast skillful to persuade the daughters of Erebus, and men were seen freed from death." Apollo's lordly son, apotheosized Aesculapius, most exclusive patron of the healing art, is not overlooked by our poet. In "Agamemnon" is found the following passage referring to Aesculapius as having been thunderbolted by Zeus at the instance of Dis for bringing back to life the most worthy Prince Hippolytus: for, "When the great physician of antiquity dared to lead the dead to life again, Zeus punished him for the deed." In "The Suppliants" Aeschylus speaks of another divine physician sprung from Apollo. Here is the passage: "The country itself where we are is the land of Apis called so formerly from the name of a physician. Come from the country of Naupactus, Apis, in reality, physician divine, son of Apollo, delivered this soil from devouring monsters." In the same drama the method of Io's fecundation is thus tersely phrased: "Zeus touched her with his hand, and by her had a son." In this play, too, allusion is made to Artemis as a midwife-goddess: "Also to keep watch over this soil ever may heroes beget other heroes, such is my prayer, and may Artemis-Hecate assist the women in child-bed."

According to chronology which may be taken as authoritative, Hippocrates was born only four years prior to the death of Aeschylus. This circumstance might seem to warrant the inference that Greek medicine during the active career of the Father of tragic drama was in an embryonic and crude state. But such a conclusion is far from the truth. As already remarked, there was medical science and art in Greece before the Father of medicine, and that, too, of extent and order not to be despised. Worthily prominent were the several medical schools, among which Cnidos and Cos perhaps rank first as to fame and influence. Rivals, at some points even antagonists, these centers of medicine assiduously and successfully cultivated learning and practice. So that when Hippocrates came he found awaiting him the task of commentator and organizer, as well as that of pathfinder. Aeschylus gives us a few glimpses of tenets prevailing in the medicine of his day. A doctrine of the physiology of the period was that in the process of reproduction the male furnishes a complete germ, and that the female is merely its host—that the father is the true generator, and the mother only the asylum of embryonic life. This view was conspicuously advanced by Pythagoras, and maintained by the school of Cortona which he founded. The implied conception is exactly analogous to that of depositing seed in its exclusive soil. It is said of a celebrated philosopher of Athens that, when surprised in the act of sexual intercourse outside the matrimonial pale, and bantered by a question as to what he was doing, he snapped back the reply, "I am planting a man." Aeschylus bases upon this doctrine his justification of Orestes as the avenger of Agamemnon against Clytemnestra. In "The Eumenides" he makes Apollo say: "You are a mother, and your child, as asserted, it is not you in fact who has given life to him. You are but the nurse of the new-born germ. The real generator is the one to whom pertains the initiative. The mother, stranger to the guest that she has received, shelters the infant to the end, if Heaven does not intervene."

Dreams figured prominently in the healing art of the time of our poet. To them was assigned much importance in temple medicine especially, even in that of the great temple of Aesculapius at Epidaurus. To this principle Aeschylus in "The Eumenides" makes reference thus—"At night when one sleeps the sight of the spirit is on account of it only more piercing; during the day one is often purblind." And just so to dementia was attributed peculiar significance. Our author in "Agamemnon" has to say about it this—"It exalts the audacity of mortals, this sad counsellor of misdoing, madness, mother of all crimes."

We find in "Agamemnon" the sage reflection, "Robust as it may be, fatally health lies close to suffering." In the same play a stroke is delivered to supernaturalism in this passage—"Moreover there are no words capable of replacing a dead man on his feet." In "Prometheus Bound" is presented this judgment—"For the sick it is an alleviation to know in advance correctly all that he must yet suffer"—a rule that might properly apply to Prometheus, but of doubtful application to most of his mortal *protégés*. By reason of its intense human interest the following passage from "The Coephori" may be given—Orestes' old nurse speaks—"An infant in the cradle can not say anything. It has hunger, it has thirst, it makes water upon impulse,

for with children at this age the belly will not wait. It is necessary to divine all. One can easily figure that I have often in this way been taken unawares. Then there were swaddling-clothes to wash; for as to laundress and nurse they are one and the same."

Aeschylus occasionally employs metaphor and illustration with a flavor, more or less intimate, of medical thought in certain of its modes. Familiar to modern ears are these figures of speech taken from "Agamemnon"—"A remedy even more terrible than the malady," and "She has sung the song of the swan." In "The Choephori," indicating a palace in mourning, Clytemnestra inquires, "What does this mean? Why such crying in the house?" The porter replies, "The dead kill the living, that is what I have to say." In "Prometheus Bound" Ocean says, "What! dost thou not know, Prometheus, that of this ulcer, wrath, the doctor is the spoken word?" In the same drama Prometheus asserts of primitive men that, "at first, they had eyes and saw not, ears and heard not—beings floating as in our dreams, during thousands of years nothing distinct for them, all was confused, all was befogged." Then to Prometheus is said, "Maladroit physician! surprised by evil behold thee without resource! Thou knowest not what to do for thyself, how to heal thyself."

The forecited excerpts represent rather completely perhaps the work of Aeschylus remaining to us of medical interest more strictly. But there is besides in him a large human element that can not fail to be of concern to the student of medicine and its auxiliary sciences. To the doctor with superlative relevancy may be ascribed the oft-quoted line of Terence—"I am a man, and I hold that nothing pertaining to humanity is foreign to me." Let us, then, briefly glance at the attitude of Aeschylus toward a few of the questions relating to man's nature and existence. One of the things most evident in the Father of tragedy is his fatalism. He is the arch-apostle of destiny. At the very center of his thought is the idea that what is to be will be. In no creed and in no other mind is predestination more vitally, more ineradicably imbedded. This from "The Choephori"—"Recollect that, free or submitted to the power of another, the master of us all is destiny." This from "Prometheus Bound"—"Let us bear as lightly as possible the destiny fixed for us, well convinced that with indomitable necessity there is no struggle possible." And again this—"Fatality ever prowls around us. She falls upon this one today, tomorrow upon that one." A preserved fragment is this —"Let one be riddled with wounds none the less one does not die of them if his day has not arrived. And by constantly staying at his fireside none the less one does not elude the term set by destiny." Even the gods are not exempt. Returning to "Prometheus Bound," with regard to "the triple Moira, the sombre Erinyes," the agents of destiny, the question is asked, "And may it be that Zeus, also, is subject to their power?" The reply is, "From the law of destiny he can not emancipate himself."

Aeschylus is, also, the mouthpiece of the principle of inevitable retribution, of inexorable vengeance. In "Agamemnon" he says—"Neither sighs, nor libations, nor tears can disarm the implacable wrath of the goddesses without hearthstone." In "The Eumenides" he makes the terrible Moira exclaim —"But who, also, among mortals is not seized with respect, nor enters into fright, at the name of that dread power which I have been made by destiny and the munificence of the gods? My prerogatives are not of yesterday. I, too, have a cult, wholly relegated as I am to the under-world, without sun, in darkness." But Aeschylus' attitude toward *lex talionis* is not one of admiration or even commendation. Rather does he manifest repugnance and horror in his portrayals of cold-blooded, pitiless vengeance. Again in "The Eumenides" he refers to the Erinyes as, "The unclean virgins, the hags, the superannuated females, for which has no liking neither god, nor man, nor beast; for the evil they have done committed to the dismal sojourn of crime, in the depths of Tartarus, objects of loathing alike to mortals and to the dwellers of Olympus." It is Apollo who speaks thus, afterward driving the unsightly sisters from his temple with this imprecation—"This is not a dwelling suited to you. Go where heads fall, where justice digs out eyes, where the blade blasts at its source the germ of new generations, where all is strewn with the litter of punishments and with palpitating limbs. The sharp cries of those stoned, the lamentations without end of the unfortunate nailed to the pale—for you those are your orgies, your atmosphere of feast, your pleasures, you, miserable refuse of immortals. Go, it is there that your shocking lineaments will find a becoming place. The den of the lion gorged with blood, that is a shelter worthy of you."

Aeschylus' pictures of human life show little of roseate hue. The deeper, graver shades largely predominate. The following passages which we quote collectively are selected as representative from a longer list. "Vanity of human things! Good-fortune, a shadow suffices to destroy it." "Poor human species! how ephemeral is thy wisdom, nothing solid, shade of smoke." "By thousands the earth nourishes scourges for our consternation and our punishment." "Of the beings of the articulate word none enjoys good-fortune without mixture." "The ills of humanity every man should expectantly await." "What value has life for him who has only to suffer?" "Better for the unfortunate never to have been born than to see the light of day." Aeschylus does not leaves us without a philosophy of life. We cite in instance these quotations—"Ah! the ideal is to be sheltered against suffering, with a just heart, content with one's lot." "Even in times of distress and bitterness let your soul be joyous each day." "Ah, well! is it by excitedly rushing from stem to stern that the pilot shall succeed in saving all when the ship is tried by the waves of the sea?" Homer's conception of loss and pain and grief and woe, as well as his attitude toward these, this wail from the "Iliad" sets forth—"Whatsoever may be our afflictions let us confine them within our soul; for of what use are tears? To live in sorrow, such is the lot assigned to mortals by the gods." It remained for Aeschylus to rise to nobler heights of vision and of faith. As a very prophet of the Infinite Unseen in "Agamemnon" he thus speaks—"This law is from Zeus—at the price of pain, knowledge. Drop by drop until we sleep, falls upon our hearts the sharp remembrance of sorrow; and in spite of us wisdom comes."

As Aeschylus stands face to face with the mystery of death there comes into his poetry a note of sadness, even of pain. How could it be otherwise in the movement of a mind at once powerful and sympathetic that was wont to strip the veil from truth? And yet with Aeschylus the hereafter is not

a realm of gloom. Hope and trust make him death's master. Occupying first the standpoint of material manifestation, and speaking in terms of earth and mortality, he voices in various places these reflections—"Ashes, all that remains of a man, a vase encloses." "Transmit them to the earth herself, that produces all, nourishing womb where all reenter to fecundate it anew." "High as may be our cries, exasperated as may be our fury, silently death reduces us to dust." "Alone among the divinities, death does not care for offerings. Victims, libations, nothing can bend her. For her there is no altar, for her no pæan; for alone among the gods she remains inaccessible to the sweetnesses of prayer."

From a loftier, serener plane of contemplation come the following utterances of Aeschylus. "Death is deliverance. No more griefs which crush the soul!" "How unjust is the aversion of men for death, this highway the most sure out of the evils that beset them!" "Oh, death! sovereign remedy, deign, deign to come to me! Thou only healest incurable ills. Once dead, no more anguish."

Upward again soars Aeschylus on the pinions of his mighty genius. His flight has placed him on a plane free from every fleck of cloud or mist, commanding all time and space. Listen to him now in "Prometheus Bound." "Then upon me falls the serpent of fire, the disheveled-haired flame, whilst the ether is in turmoil, stunnel by the uproar of thunder, by the shock of savage hurricanes. The earth trembles on its base, uprooted by the whirlwind, while the surging of the sea in its hoarse roarings mounts to the heaven, gigantically hurled upon the way of the stars. Until at last, engulfed in black Tartarus, Zeus casts my body, driven to and fro, into a giddy swirl without end, irresistible. Nevertheless, for all that I shall not die." But he who thus speaks is Prometheus, scion of an immortal race. Yet hear again Aeschylus in "The Choephori." Now he makes mortals address a mortal. By the libation-bearers to Orestes are spoken these words—"Child, the soul of one dead survives the burning bite of the funeral pile." And thus, as with his own proud Titan in spite of rock and chains and vulture, so with our lordly Aeschylus the ultimate tone, majestic, solemn, is a shout of defiance, of exultation, of victory.

WHAT THE GENERAL PRACTITIONER SHOULD KNOW ABOUT THE THERAPY OF SYPHILIS.*

By ADOLPH ROSTENBERG, M.D.,

NEW YORK.

DERMATOLOGIST TO THE BRONX HOSPITAL AND DISPENSARY AND GERMAN HOSPITAL O.P.D.

At the annual meeting of the American Medical Association in 1914, during the discussion in the symposium on syphilis the assertion was made by some prominent syphilographers that 99 per cent. of all general practitioners in this country were incapable of treating syphilis according to the advocated standard of to-day.

To say the least, this is rather a broad statement, and if really true, would indicate an awful state of affairs, as every general practitioner handles cases of syphilis and everybody will admit that syphilis is not an irrelevant disease. According to Blaschko 33 per cent. of syphilitics die of the disease, and in 50 per cent. of these cases death is caused by syphilis of a vital organ. Therefore the general practitioner should know how to treat this terrible scourge which, when taken in time, is readily amenable to treatment, but when left unrecognized becomes one of the worst menaces to the welfare of humanity.

Now, has the last word been spoken in syphilis therapy? Certainly not. In spite of all the latest investigations there is still even among our leaders a wide discrepancy as to the best methods of combating this disease. Wechselmann, for instance, in the new Virchow Krankenhaus, in Berlin, who undoubtedly has as much, if not more, experience than any other syphilographer, employs only salvarsan; and Buschke, his associate in the same hospital, rejects salvarsan altogether and still adheres to mercury.

Between these two extremes, however, the consensus of opinion of nearly all other investigators is that the rational therapy lies in a combination of both these drugs. We know that both are chemical agents which either kill the spirochetes or at least arrest their development. By experiments it has been shown that each one attacks the microorganism in a different way, therefore it seems plausible enough to use both weapons simultaneously against this disease. Furtherfore, the combination of the two drugs is not only more effectual than each alone, but the toxic effects on the patient's organism are less dangerous. Salvarsan, by killing the spirochetes, sets free a large amount of endotoxins which would be greatly diminished if we used mercury immediately before or right after. Furthermore, the dose of each drug, in order to have its effects, will also be much smaller when used in combination than when each alone is employed.

The best results of our therapy we will naturally expect when a case presents itself in its earliest primary stage. By experiments on animals, according to Neisser, it has been shown that the syphilitic virus circulates free in the blood in the very beginning. Salvarsan, injected into the vein, will meet the enemy in the open field and achieve a great victory; in fact, perhaps the greatest result we could hope for, namely, a complete sterilization of the patient. But to achieve such a brilliant result two important preliminary conditions must be fulfilled. Firstly, we must educate our patients not to hide their venereal diseases and not to go to a friend or a quack for treatment in the beginning; and secondly, we must be able to make an early diagnosis; the old dictum, wait for secondaries before you start treatment, would be considered ignorance and negligence to-day. We have to make our diagnosis at once and start treatment accordingly. Unfortunately, the Wassermann test—in my estimation the greatest of the three discoveries in modern syphilography—fails us here; we rarely get a positive reaction before the sixth week after the infection. Therefore, should we be in the slightest doubt from a macroscopical examination as to the real nature of the chancre, it is our duty to look for confirming evidence and to examine for the spirochete. But we must look for them in the right way. The staining method with India ink, which is becoming rather prevalent in this country on account of its simplicity, is not reliable. The dark field illumination should be the method of choice; here we often find the spirochete at a first glance and in large numbers, while the same specimen

*Read before the Bronx County Medical Society, November 18, 1914.

stained with India ink and examined for a long while does not reveal any at all.

Having thus established our diagnosis we must begin our treatment at once. Now we have the best chance not only to cure the chancre but to cure the disease. The spirochetes are still localized in the primary lesion and perhaps the nearest lymphnodes. A single dose of salvarsan may kill them all or at least paralyze their further development and prevent their further spreading. The result would be Ehrlich's therapia sterilisans magna, which, indeed, is not an impossibility in such an early case. But, unfortunately, so many recurrences have been observed since this dictum of Ehrlich was published that nobody to-day, not even Ehrlich himself, stops at one injection; we give several and use mercury in addition. Should we excise the chancre? A good many authors recommend this operation, if feasible. I myself have never done it and only insist upon a clean surgical dressing, using calomel as a dusting powder.

I start my treatment with from 0.30-0.45 of neosalvarsan, according to sex, weight, and robustness of the patient. I personally use neosalvarsan almost exclusively and believe its effects to be as good as from old salvarsan, although a good many claim to have seen better and more lasting results from the latter. But the easy preparation of neosalvarsan, which dissolves readily in water without any addition, recommends its use more to the general practioner. Besides, it is easier to use neosalvarsan in a concentrated solution, a method which is simple and I think safer than the infusion method. The latter one is undoubtedly known to all of you and I need not describe it in detail. I only wish to draw your attention to the importance of using a straight needle instead of a curved one, which readily becomes impermeable. The so-called concentrated method does away with all cumbersome apparatus. The drug is dissolved in 10 c.c. of freshly distilled and sterilized water, drawn up in a record syringe, and slowly injected in the median vein under aseptic precautions; the mixing of blood with the solution will show that the vein has been correctly entered. This is a very simple procedure and can be readily performed in one's office. I always caution my patients to lie down right after getting home, but I know that even this has been neglected in a good many instances and no ill results have been noticed. I use the direct intravenous method exclusively, except in cases in which, because of a very fat arm or poorly developed veins, an introduction of the needle would be impossible without a dissection of the vein. To avoid this rather objectionable operation, I use the intramuscular method in these cases, either in a watery solution or an oily suspension, both painful compared with the absolute painless intravenous method. After the first injection, I give my patients 4 or 5 more in this way, the second 8 or 10 days after the first, and if the first was well tolerated, a dose of from 0.45 to 0.60, then 2 weeks afterwards from 0.60 to 0.75, and repeated in another 2 or 3 weeks, gradually increasing to 0.9. Immediately after the first injection of neosalvarsan I give weekly injections of 10 minims of a 10 to 20 per cent. emulsion of the salicylate of mercury—10 to 15 in all. This procedure constitutes one course of treatment. About 4 weeks after the last injection I control my results by taking a Wassermann test, and in a good many instances the report will be negative, which means that the patient is apparently cured and his infection has been aborted. Should we stop now with all further treatment and control our patient's future only by subsequent repeated Wassermann examinations? Some syphilographers proceed in this way and report a number of abortive cures in cases observed over a few years which remained serologically and clinically free from symptoms. I have seen such cases abroad, and Fordyce, among others in this country, reports a series of thirty abortive cases—fifteen of them infected as far back as four years ago; some of these patients have even been reported to have acquired a syphilitic reinfection, which, if surely proven, would be a positive evidence of the possibility of an abortive cure.

But in spite of these facts, I rather feel inclined to believe, and I follow here the majority, that it would be safer to extend the treatment even in spite of negative symptoms for a period of about two years, giving two to three courses as described above in the first year and one to two in the following. Now if two years have thus elapsed and the patient has clinically and serologically been free from all symptoms, can we pronounce him absolutely cured and promise him that he will remain well? In all probability yes, but if the patient is very anxious and if he contemplates marriage, we have two more tests which will conclusively prove his status. The first one is a provocative Wassermann test, as proposed by Gennerich and Milian. The patient gets a medium dose of salvarsan, and his blood is examined for two weeks, daily for one week and then on the fourteenth day. If the Wassermann at any time becomes positive again it would prove that there was a latent focus of living spirochetes somewhere, which the salvarsan incited to activity again, proving that the patient had not been cured as yet. The second test is an examination of the cerebrospinal fluid, especially indicated where the patient has at any time shown some cerebrospinal symptoms, as severe headaches and dizziness. Here we examine for the so-called four phases of Nonne, which are a positive blood Wassermann, a positive spinal-fluid Wassermann, a lymphocytosis, and a positive globulin reaction. The details of these reactions belong to the laboratory and do not concern the general practitioner.

Hitherto we have been considering the treatment advised in the primary stage of syphilis. But the great majority of our patients consult us for the first time when the secondaries have developed, usually with a roseola, mucous patches, papules, a general adenopathy, etc., sometimes the induration of the primary lesion being still in evidence. The clinical diagnosis as a rule does not offer much difficulty here, but to corroborate the same we should make a Wassermann test which in a hundred per cent. will be positive now. In this stage the patient is a great menace to society, as his lesions abound in spirochetes and even an innocent infection through contact is not impossible. In salvarsan we have a most powerful agent to achieve a rapid symptomatic cure. But, as explained before, the effects of salvarsan might be too explosive now, as the large number of killed spirochetes may liberate a too large amount of dangerous endotoxins. Therefore, we should prepare the defeat of the spirochetes with one to two injections of the milder acting mercury and then follow with salvarsan in the same way as outlined before. In this stage, we can not expect an abortive cure; the recurrences will be frequent in spite of rational

treatment. An intermittent salvarsan-mercury therapy extending over three to five years and even longer may be necessary, the Wassermann test with all its modifications being our only guide as to a final cure. Heidingsfeld investigated a series of 442 cases being treated *lege artis* for two and a half years and found only 77 per cent. consecutive negative Wassermann reactions, whereas 23 per cent., in spite of all treatment and absence of clinical symptoms, persisted in a positive reaction. What shall be done with these so-called latent cases, where the spirochetes apparently have become salvarsan-fast; should we still persist in treating them? According to the experience of Heidingsfeld the results are better when such cases are left alone for a while, treated only with general tonics or other arsenic preparations like the cacodylate of sodium. Some of those persistent plus Wassermann reactions thus became negative finally.

In the very late forms of syphilis, known as the tertiary stage, where besides the skin and mucous membranes, the bones and viscera also become affected, we should not forget in addition to salvarsan and mercury our old standby potassium iodide, and it should be potassium and not sodium iodide, or any of the modern organic iodine preparations, and only large doses are effective. If the patient does not show any idiosyncrasy to iodine, I very soon run up the dose to 100 grains a day, given either in vichy or milk. Potassium iodide is also very useful in the so-called malignant forms of lues. But here salvarsan has shown its most brilliant effects and has actually been a lifesaver. Lesions which formerly would have led to mutilation or death by causing destruction of bones or other important organs or perforations of large blood-vessels, yield sometimes to one injection of salvarsan, the progress is arrested and eventually a complete cure achieved. In addition to salvarsan we use here the more active calomel injections instead of those of salicylate of mercury, which are also given as an emulsion and in the same strength as the latter.

A routine examination of the spinal fluid has shown that a syphilitic infection of the nervous system is very prevalent. Ravaut in France has shown spinal fluid changes in about 70 per cent. of secondary syphilis. Fordyce concludes in his treatise on the treatment of syphilis of the nervous system that upon the dissemination of the spirochetes throughout the body the nervous system bears the brunt of this general invasion. This may manifest itself as a meningitis with or without clinical signs and with only spinal fluid changes. It has also been shown that the involvement of the nervous system takes place very early. Cerebral syphilis has been seen as early as four months after the infection, and I myself have seen a case of cerebral facial palsy simultaneously with the roseola. Naunyn says that the majority of infections of the nervous system take place during the first year, after which there is a decrease in frequency.

The brilliant discovery by Noguchi of living spirochetes in the nerve tissues of paretics and tabetics proves without a doubt that these cases can no longer be considered as para- or metasyphilitic infections but as true cases of syphilis of the nervous system. In the therapy of these unfortunate conditions salvarsan was tried with great expectations. Unfortunately the results were rather poor; in paresis almost nil, in tabes a little better.

The positive spinal fluid findings in these cases, have therefore recently suggested the method of introducing the remedy directly in the cerebrospinal canal. The rather poor results obtained heretofore are explained by the fact that the salvarsan, because of anatomical conditions, cannot enter through the blood into the spinal fluid, and thus does not come into direct contact with the spirochetes deposited in the nerve tissues. Therefore, Swift and Ellis have advised the injection of the so-called salvarsanized blood-serum directly into the spinal canal. The technique of this is as follows: One hour after an ordinary intravenous dose of salvarsan about 40 c.c. of blood is withdrawn, sufficient to produce 12 c.c. of serum. This serum is heated and diluted to 30 c.c. with decinormal saline solution. This mixture then is injected into the spinal canal after an equal amount of spinal fluid has been withdrawn, after which the patient is kept in bed for 24 hours.* The results obtained by this method are very encouraging, but still too recent to allow of any definite conclusions.

In the treatment of hereditary and acquired syphilis in children, we also use salvarsan along with mercury. The technique here is naturally more difficult. The intravenous method is also the most rational one. If the median vein on the elbow is selected, a dissection will be necessary in most cases; to avoid this the jugular or, according to Holt, one of the veins of the head, especially the postauricular, may be used, as these fill up greatly when the child cries, thus facilitating the entrance of the needle. The dose in infants up to 8 months is about 0.075 of neosalvarsan; in older children about 5 mgr. to each kilogram of bodyweight. As children stand mercury well we use in addition calomel or inunctions of gray ointment, and for infants bichloride baths by putting one ordinary bichloride tablet in 5 gallons of water.

From the foregoing it appears that salvarsan is our foremost drug in the therapy of syphilis today. But we also should know that it is by no means an indifferent drug and before we can safely employ it we should be familiar with its by-effects, contraindications, and possible dangers. We will realize this when we remember that salvarsan contains 34 per cent. of pure arsenic. Chemistry teaches us that arsenic coagulates albumin, and when the cell is overirritated, especially the excretory epithelial cell, its function is impaired or arrested entirely. If the kidney is involved, anuria will set in, the elimination of salvarsan will become impossible, arsenic will accumulate in the body and produce its toxic and fatal effects on the vital centers. Therefore, we must exclude cases in which elimination would be imperfect, as in diseases of the liver, kidneys, and intestines. Severe forms of circulatory disturbances as uncompensated heart lesions, myocarditis, aneurysm, advanced forms of arteriosclerosis, advanced tuberculosis, all cachectic conditions, and alcoholism preclude its use or at least demand very great caution, provided all these conditions have not been directly caused by the patient's syphilitic infection itself.

If these precautions are carefully observed, 99.9 per cent. of all salvarsan injections, according to

*The serum is of additional value, as it may be assumed to contain important antibodies which may also play a large rôle in the result.

Neisser, will be entirely harmless or at least followed only by slight after effects, which are almost negligible, such as a moderate rise in temperature, chilly sensations, some vomiting and diarrhea occurring from 4 to 8 hours after the injection and usually disappearing entirely the following day. According to Wechselmann and a few others these by-effects are not due to the salvarsan at all, but to impurities in the water, containing dead saprophytic bacteria and chemical substances, originating from the glass vessels in use, the so-called "Glass and Wasserfehler." This explanation seems rather very far fetched, and the majority of men to-day consider these phenomena as toxic effects due to the arsenic.

Another phenomenon is the so-called Jarisch-Herxheimer reaction, a vasomotor disturbance, showing itself to a different degree in different organs, whereby the specific lesions assume a more pronounced character; the roseola, for example, appears larger and of a deeper reddish hue, which lasts for a few days. The cause of this seems to lie in a liberation of endotoxins during the killing of the spirochetes, these toxins dilating the capillaries and causing an edema in the adjacent tissues.

Some authors have explained the appearance of the so much feared "neurorecidives" as a late Herxheimer reaction. These neurorecidives are forms of paresis or paralysis of the cerebral nerves, especially the acusticus, opticus and facialis, also meningeal irritations, leading to epileptiform attacks; quite a number of such cases followed the use of salvarsan when it was first introduced. The experience with atoxyl, an arsenic preparation, which led to total blindness and deafness, was still fresh in the memory of the profession and naturally many voices were raised, condemning salvarsan also. But soon other investigators, as Ehrlich, Wechselman, and Neisser, tried to show that it could not be the salvarsan which caused this damage, as the only cure for a neurorecidive was another prompt injection of salvarsan. They believe the cause to be insufficient treatment, whereby some foci of unkilled spirochetes are left behind, especially in the cerebrospinal fluid, where a penetration of the salvarsan by diffusion had not taken place. These remaining foci, thus only irritated, will assume the character of a primary sore, that is, they will produce a severe local inflammatory reaction, causing pressure on the affected nerves, especially where they enter the small foramina in the skull.

In contradiction to this explanation by Ehrlich and his followers, Finger and others claim that salvarsan, because of its neurotropic properties, creates a *locus minoris resistentiæ* in the central nervous system, so that the syphilitic process finds there an easier foothold, or else the infection causes a lessened resistance of the nervous system to the toxic effects of the salvarsan. Others believe that the salvarsan is without influence and that these neurorecidives would have appeared anyway in the natural course of the disease. Whatever the real cause may be, we see these complications much more rarely now since we do not use such large single doses of salvarsan in the beginning and since we use mercury with it.

Fortunately, these neurorecidives are in most cases not fatal, but in spite of all precautions fatalities after the use of salvarsan have occurred and, I fear, will occur in the future, though much more rarely. Mentberger in Strassburg has compiled an analysis of all the salvarsan deaths which had been reported up to 1914 (274 in all), but a more thorough revision by Schmitt in Würzburg brought this number down to 172, showing that 102 of these reported cases could not stand the test. The victims were mostly young individuals between 20 to 40, who, except for their lues, had intact internal organs and an unaffected nervous system. The fatalities occurred in all the stages of syphilis and independent of the dose and number of the salvarsan injections. In a few of these cases we find that the patient died suddenly immediately after the injection. A more frequent type showed a more subacute form coming on in a day or so after the injection. The symptoms were severe headaches, general weakness, vomiting, diarrhea, often incontinence of the sphincters, dyspnea, cyanosis, convulsions, and coma followed by death in three or four days. The autopsy revealed a serous meningitis or punctate hemorrhages in the brain, indicating a hemorrhagic encephalitis. In the third group there was a total of partial suppression of urine with hematuria and convulsions, followed by death, the autopsy showing a severe degeneration of the kidneys and liver, just as is experimentally found in arsenical poisoning. But even in these desperate cases, according to very recent investigations, a promising remedy has seemingly been advised. Ehrlich, discussing, in the *British Medical Journal* in one of the issues of May, 1914, the type of salvarsan deaths apparently caused by hemorrhagic encephalitis, points out that the enormous dilatation of the blood-vessels found in these cases was probably due to the fact that the normal regulator of the vascular system, adrenalin, was not present in sufficient quantity in the blood, this condition being found in cases of Addison's disease and in hypoplastic processes occurring in the suprarenals causing a so-called status thymolymphaticus. Melian in Paris took up this point and has shown that accidents, developing immediately after an injection of salvarsan, characterized by blue-red swelling of the face, lips and eyes, and dyspnea, may be completely avoided if adrenalin is injected previous to the salvarsan. He also showed that severe diarrhea and suppression of urine threatening life was cured by repeated injections of adrenlin. He even has saved an otherwise hopeless case of encephalitis by means of an energetic adrenalin treatment. The same favorable results from adrenalin have been reported by a few other men in similar cases.

But even granted that adrenalin will not be a panacea for all salvarsan fatalities in the future, these few deaths will be offset by the innumerable benefits derived from the millions of successful injections. Chloroform and ether have and will cause deaths, but we have not abandoned these anesthetics for that reason. Therefore we must admit that salvarsan is still our foremost remedy in the treatment of syphilis and to try to get along without it would be, to say the least, irrational.

Milk-Borne Scarlet Fever.—O. R. Eichel reports an epidemic of scarlet fever in Albany, N. Y., traced to a dairyman suffering from this disease. The surprising fact is that none of the families supplied with milk by this dairyman had any cases of scarlet fever. These were found to occur in families supplied by a farm that had been visited by the above-mentioned dairyman. —*Monthly Bulletin, New York State Department of Health.*

UNCONSCIOUS MENTAL PHENOMENA.*

By JOHN INGLIS, A.M., M.D.,
DENVER, COLO.

To know the mind pathologically, we must know the mind psychologically. It is impossible to know pathology without first knowing physiology. Every disease of the human body has its psychological element. No subject is of more general interest among the sciences to-day than is that of psychological phenomena. Knowledge has become diffuse, but this diffuseness has not always led to depth. Our morning paper will talk glibly of psychological facts; the weekly home journal will prate of the subconscious mind; the talk of the drawing room will often take on a certain psychological vocabulary, one fundamental question will reveal the fact that it is vocabulary only. All these things show simply the present day trend of thought. Much of it is an effort to be erudite without traveling the one road that leads to all learning. Psychology appeals to the general reading public because there is a certain mystery around it. Men write psychological articles who have never spent an hour in a psychological laboratory.

Medicine and psychology have much in common. Every physician has seen frequently in his own practice the psychological effect of a medicine. A drug that could not possibly cause emesis suddenly becomes a powerful emetic by association. Likewise I have seen a harmless placebo become a cathartic simply through its psychological effect. These are observations of every day occurrence. Every physician has heard: "Doctor, I can't take" so and so. Only the other day a woman whose case I had scarcely begun to diagnose said: "Whatever you do, don't give me aspirin, it does not agree with me. I can't even take a grain of it." She did take, however, five grain powders of it to saturation, but the prescription called for acetyl-salicylic acid and the powders were colored black with charcoal. Had they been white it would be true she could not have taken this drug. The psychological effect of prescriptions should never be lost sight of in therapeutics. The success of the same line of treatment in the hands of one physician, that has failed in those of another, is often due to an understanding of psychology. No profession has the opportunity of putting psychology into practical use more than the medical, and no profession needs to understand it more. Medically, surgically, obstetrically, psychology will be an aid to the doctor. Crile's Anoci-association in surgery is founded on psychology. The surgeon who carries into the operating room a child or an adult, "frightened to death," and begins the administration of an anesthetic without allaying the mental fear, is guilty of willfully neglecting the use of one of the most powerful influences in establishing resistance.

The foundation of psychology is consciousness. Consciousness may be defined as the one common and abiding form of all mental states; without it, mind is not. It is that without which there is no mind as we know mind. Consciousness itself is not an attribute of the mind or a mental organ. It is the one essential element that characterizes mind as purely mental, apart from its physical manifestations. Unconscious mental phenomena is a term much in use at present to explain certain mental states. To one school these phenomena represent a subconscious mind, a mysterious sort of a second mind which all unknown holds memories and impressions lost to the present consciousness, a sort of substratum mind. To another school they represent simply facts of least consciousness.

What is consciousness? The study of consciousness begins with the infant. It is probable that the beginning of consciousness is a mass of sensations. The first movements of the body are random movements having their origin in nervous sensations. In this early stage of consciousness these movements represent muscular sensations, touch predominating. The development of conciousness depends in great measure on the development of the body. The brain itself grows rapidly in size and complex functions. Gradually the movements of the body take on a purpose. The child moves at first from a sensation of physical discomfort. Then comes the differentiation of sensations. Touch and muscular sense give the baby in time the form of its own body. The infant will reach for the moon or a bright light far beyond its reach because it has not yet learned to place external objects as distinct from itself. In time it learns what is "I" from what is "not I," and from this comes the notion of self-consciousness. In the child, memory and association are weak and indefinite. It requires a strong excitation to amuse them. The first whistle of the fond father causes the child to look in any direction for the sound. Attention at first is very vague but soon becomes definite, the sight and sound are soon associated, the smile follows. Attention is simply active consciousness. Consciousness may be said to be like our view from a mountain top. The object in direct line of vision is most distinct, everything else in sight is seen more or less distinctly in proportion to its distance from the line of vision. So the area of consciousness represents the total presentations at any one time in consciousness distinct or vague. In a paper limited to fifteen minutes it is only possible to outline a subject that, presented in full, would require a volume.

The facts of consciousness compared with unconscious phenomena may be illustrated in this way: We sit in a room like this, papers are being read, we are conscious of the fact. If actively conscious we focus our attention upon them. This becomes to consciousness what the direct point of vision is to the sight. Yet in addition to this, we are vaguely conscious of a hundred other things. We are conscious in an indefinite sort of way that the room has windows and chairs, that some one else is sitting behind us, but to these things we are passive. All these things pass through the mind in kaleidoscopic view. A newsboy rushes past the window shouting "Extra, big battle near Paris!" Instantly attention is transferred thousands of miles away. Those of us who have been in Paris immediately think of her streets and boulevards, her forts, her government, the armies, the battle; and so ideas pass from the outer circle of things subconscious—passively conscious, and suddenly into the bright focus of active consciousness. It is this passing from the outer circle of consciousness to the center that gives rise to the argument for unconscious mental phenomena. Are the sensations upon which this process proceeds unconscious or conscious? The whole problem is involved in the answer to this question.

Those who labor to establish the validity of unconscious mental phenomena argue it, as Prof. Baldwin says, from causation, i.e., if a cause produces a certain effect, part of that cause will pro-

*Read before the Colorado State Medical Society, 1914.

duce part of the effect. As physicians, we know that this argument is not sound. Five grains of strychnine will kill, but 1/20 grain of the same will not kill, it may even save life. If a man drinks a half pint of whiskey, we say he is drunk, but it does not follow that a dram of whiskey makes him 1/64 drunk. We look out over a green field, we have a consciousness of green, but each blade of grass does not reach consciousness in succession but at once. We stand on the seashore, we hear the beating of the waves, we call it the roar of the sea, yet each wave is not producing a mental effect separately—what each wave produces is merely a physical effect. All arguments for unconscious mental states fall into some such line of argument. We are told as an example, that the miller is unconscious that his mill is running. We sit reading in a room alone, the clock is ticking, we are told that this is an unconscious mental phenomenon, that we are unconscious of the clock ticking. We walk and are said to be unconscious of the pavement; yet, let the mill stop running, the miller knows it immediately, the clock stops and soon we are aware of it. We step from the pavement onto the sod and we find we were passively conscious of the pavement. The fact is the miller was conscious of his mill, we were conscious that the clock was ticking. Logically this is no argument for the unconscious at all for, as Mark Baldwin of Johns Hopkins says: "It is contradicted by the conclusion in the case; for if the whole effect is a fact of consciousness the *partial* effect must be a fact of consciousness also"; consequently it is a conscious fact and not an unconscious one.

This brings us to the question of the subconscious mind; what is it? The idea of a subconscious mind has taken a prominent place in recent years in all psychological discussion. It is an effort to give us an hypothesis to account for certain so-called unconscious mental phenomena. It is, it must be remembered, an hypothesis only. That it has a *de facto* existence has not been proven. It is supposed to be a mind beneath our intellect, feeling, and will —a sort of substratum of the soul; a kind of underlying mind that defies all analysis. We feel it but it is never subject to our introspection. A man feels that some great discovery is pent up within him, yet he cannot develop it, or he feels that if only he could express himself, he could produce a "Hamlet" or a "Paradise Lost." These, we are told, are the efforts of the subconscious mind to give expression through the conscious mind. The hypothesis acounts easily for all unconscious mental phenomena by referring them immediately to the subconscious mind. It is the facility with which this is done that has given rise to the idea of the subconscious mind. But it is a well established fact in science that of two explanations of a given phenomenon the simpler explanation is usually correct.

We do not need to suppose or to invent a subconscious mind to account for these phenomena. Degrees of consciousness itself will explain them all. For example, images once in consciousness have fallen below the plane of consciousness, but they will immediately rise into consciousness again when the stimulation of the cerebral centres is sufficient to draw attention to them. There is a point of least consciousness for each sense; a least perceptible touch, a least perceptible taste, a least perceptible sound, etc. If we call unconscious phenomena excitations of less strength, and all states which have been in consciousness as now simply subconscious, and all states which are now present in the mind as conscious, we have simply and fully classified all these phenomena without resort to a subconscious mind. In other words, degrees of consciousness account for all the phenomena the subconscious mind is supposed to be needed to account for them.

Unconscious phenomena are physiological phenomena; phenomena just above the physiological are subconscious. Just beyond the subconscious is the large field of the passively conscious—and that to which our attention is specifically directed is the present active consciousness. As Binet says: "If there be unconscious mental phenomena we know absolutely nothing about them," or to describe the subconscious mind in the words of Howell T. Pershing before a former meeting of this society: "It is a figment of the imagination." Münsterberg says: "The subconscious mind may be described in three words: 'There is none.'"

How, then, are we to account for so-called unconscious mental phenomena? In the first place we must remember that the physical basis of the mind is what we call cerebration and *that* of the whole sensorium. The organism as such, tends to repeat actions already performed. From this fact the mind, as it were, turns over to the body many details which are no longer mental acts of themselves, but purely organic and reflex acts. In other words, what *was* mental *becomes* simply mechanical. Consequently unconscious mental states may be accounted for from the physical side as excitations insufficient to produce a mental effect, and on the mental side as states of least consciousness. They are therefore accounted for, partly as mental and partly as physical facts.

808 Majestic Building.

A NEGLECTED FIELD OF MEDICAL CULTURE.

By T. D. Crothers, M.D.,

Hartford, Conn.

In an article entitled "Voice and Manners in Medical Practice," published in the Medical Record May 16, 1914, special attention was called to the influence of untrained voices and bad manners on the success and failure of medical men.

This paper has attracted much interest and brought out a large correspondence from medical men in all parts of the country, also several requests to take up the subject again with the view of calling attention to this neglected field of culture, and having it materialize in some tangible lectures and studies in medical colleges.

Any general observation of medical students reveals the fact of how closely they reflect manners and conduct of medical teachers and medical practitioners with whom they are associated. Whenever the student decides on medicine as his future work, there is a keen alertness to observe the manners and personalities of medical men. Both consciously and unconsciously they copy after the conduct and manners of physicians in their observation.

In a town in Pennsylvania, a physician with a very large practice was noted for carelessness of dress and general disregard of the proprieties of conventional life. His professional associates in that neighborhood were influenced by him, and in

many ways, imitated his eccentricities. His intellectual ability attracted and while his bad manners and rude conduct repelled, they were unconsciously copied.

It has been noted that quacks and irregulars who are successful in certain communities and who possess cultured manners and smooth tones of voice form a standard which young men copy more or less. Students in colleges are often duplicates of certain professors in manners and range of thought, particularly if the professor has some peculiarities that separate him from the other teachers and practitioners. Medical students of all others have to pick up ethical culture and ideas of manners, voice, and dress, befitting their work. These are things that are not born with the man but must be acquired. Home life and collegiate training do not furnish examples. While they may help to cultivate affable manners, they fail to prepare the young man for the ideal work of a physician in the sickroom and in society.

What is called ethical training in medical colleges consists often in mere formal statements of the relation of physicians to each other, to their patients, and the commercial requirements that call for exactness in certain special lines of duty, but there is no training of how to appear to the best advantage, how to develop the best culture in voice and manners, and how to impress one's patients in the best way and secure their fullest confidence. All this must be gathered from other sources.

Physicians are more carefully studied today by laymen and patients than ever before. They are supposed to represent ideal health and ideal manners, and to possess a knowledge of how to apply these in the most practical way.

Exactly what the opinion of the physician may be is often of minor importance, unless sustained by a personal culture and superiority of voice and manners. The patrons immediately consider one who is blunt, coarse-talking, and untidy in his appearance as one who is defective mentally. Without expressing this the most intelligent and the most ignorant patrons are always attracted and impressed by the kindly, musical voice, superior appearance, good manners, good language, and sympathetic ways. In pauper hospitals, the doctor with attractive dress and manners and a modulated voice is welcomed and watched with the greatest of attention. What he says is remembered longer. Teachers who give lectures at the bedside to students show remarkable variations in their influence on both patients and students. The voice and manners of the teacher often repel the patient and he shrinks and shows his antagonism.

Almost every large hospital furnishes examples of the great difference in visiting physicians, in their influence on the patients. These doctors are very often excellent men and highly trained, and yet some of them have a marked repelling influence on patients. The only explanation is want of culture, bad manners, and harsh voice. These things are not mentioned by the patient, but the hospital authorities realize that certain visiting physicians are not popular. That word is used to describe a great many things which are not expressed in words.

In actual practice, physicians often deplore their failure to retain families and inspire respect among the patients, and are constantly annoyed at being replaced with other, inferior men. In most cases it is their own fault, not their lack of knowledge, but their want of culture and faulty manners. The modern physician of today is judged from his appearance and good health. Thus a physician who is pale and anemic and apparently weak and debilitated, or one who has a bloated, over-fed look with an intensely red face suggesting beer and gormandizing, together with other marks of general debility, repels the patient who reasons that the physician who is unable to keep well himself cannot be trusted to advise on questions of health in others.

If to this is added a low monotonous tone or a high shrill falsetto voice suggesting bronchial and nasal troubles, or a discordant voice in intonations and changes, the aversion is greater. Many physicians have a very rasping inflection of tone, going through the entire scale in ordinary sentences, using words inexactly, slurring phrases, mixed up with expletives, figures, and illustrations that have little or no reference to the subject.

Other physicians use language with a military abruptness and exclamatory, commanding way, without any cause or purpose, or without reference to the subject, and all these create adverse impressions, and while the patient may not consider these other than as weaknesses, they always have an influence detrimental to the respect which the physician should have.

In all medical colleges, knowledge is the great ideal sought for; to be learned in diagnosis, to have a mass of facts and a capacity for reasoning, is considered perfection. The central fact that the physician himself should be in approximate ideal health, that his training should concentrate on himself first, developing mental and physical vigor and superior capacity to others before he can become a teacher and advise on questions that require the clearest and best judgment, is not recognized. If his voice is not cultivated, he is unable to express himself in the manner that will carry conviction.

Exactly how much he may know of the technique of diagnosis, of therapeutics or of surgery, is a secondary matter to the patient compared with his appearance of good health of body and mind, and his recognition of proprieties and requirements for the sick room and the hospital ward. The patient judges from the external appearances, the dress, the manners, the voice and the physician's apparent control of himself and ease with which he adjusts himself to the surroundings. Patients of all classes quickly recognize the departures from the normal, the timidity and weakness of the physician who shows anger, envy, and the coarser emotions, which they themselves are subject to.

Patients quickly realize the range of thought of the physician whose stories of professional life and events reflect on the weakness of human nature, and while they laugh and seem amused, always deplore statements of this kind.

Intelligent and ignorant laymen, even today, recognize that the most wonderful advances of science concerning human life, the treatment of disease, and the diminution of mortality, come from the medical profession; that they, of all others, should illustrate these marvellous changes by a degree of physical culture that is external, showing that they, themselves, have respect for the body, and its clothing, that they know the value of the voice to express the facts and the necessity and need of recognizing all the requirements of society and the sick room. There are a great many physicians who approximate this ideal, but there is a larger number who fall far below it.

The effort to raise the standard of culture in medical colleges is commendable, but fails lamentably when limited to the mass of abstract facts which the student has piled away in his brain. Studies that cannot be applied to make the student a better man physically and mentally and teach him how to use these in the most practical way are almost worthless.

College training that fails to lift the student above the beer drinking, cigarette smoking level of ignorant men, that fails to teach him how to dress with propriety and to talk with culture and clearness is lamentable. The very first elements of clear thinking and comprehension of facts necessary to determine the means for their relief, calls for the best degree of physical vigor. The tobacco and cigarette smoker destroys his voice and ability to express opinions and convince the patient. He is putting out of tune the vocal cords, and cultivating discordant tones that utterly fail to express the real facts.

The gourmand and the beer drinker destroy the nutrition of the body upon which their best efforts depend, they impair the capacity to make practical the real facts. In the same way, the faulty care of the body in loud, unfitting dress, jewelry that resembles the sporting class, and want of cleanliness and adaptability to the position he occupies still farther lower his capacity to express and to teach the facts called for.

Teachers in medical colleges are forced to adopt certain conventional customs in dress and manners, but voice culture is largely an unknown art. As a rule they have given no attention to anything but the specific topics of their lectures, never realizing that their manners, dress, and voice make more of an impression on the student than most of the facts they are teaching.

The clergyman whose training removes him largely from the currents of every day life sets up a certain superiority and spiritual elevation of manners and tone that brings with it a certain respect and reverence that is justifiable. When he gets down to the level of his audience, it is simply to urge one dominant thought of controlling the physical and elevating the spiritual of life. He approximates an iideal, but only in one direction.

The lawyer has another form of culture which concerns the mistakes and follies of human life and their legal correction. He has detective faculties to find out faults and suggest their remedies. This is limited to the external relations of life. He rarely comes into the inner circle of human growth and culture, except as a protector and guide for external relations. On the other side the physician, if his training has been correct and he has amplified it in his own life and presents this in voice, manners, and dress and in sympathy, comes into the closest relations and brings ideals and most helpful influences, not only in the treatment of disease, but in enlarging the range of human life and widening the circle of development and growth.

These facts may be illustrated by innumerable examples. Thus, one day two motors stopped in front of a millionaire's home. From one stepped a great physician who was a teacher and writer, and a most highly respected man. His appearance was that of a very commonplace business man with an air of unrest. His voice was grating and harsh. His hands were uncovered, and he hurried up the steps carrying a soiled bag in an awkward way.

From the other motor stepped a man of about the same age, neatly dressed, erect, the picture of health and serenity. His hat, clothing, gloves and shoes all indicated a professional man, and his melodious request to the driver to return in half an hour was soft and modulated.

To the street observer these two men represented very wide differences. One was a most eminent man, notwithstanding the fact that his manner and appearance were against him. The other man had a pathy to his name, and was without history of training, reputation, or standing. Some members of that family recognized in the pathy a superior man, and of course employed him. The others had doubts, and the really superior man was supplanted. The man who should have been consulted, of all others, had he been the type of good health, combined with culture of manner, dress and voice, was simply tolerated because of his reputation.

Recently a noted foreign professor gave an address to a large audience of physicians which was illustrated by a number of hospital patients. His description of the disease, the technique, and his wealth of clinical facts charmed his hearers, but his coarse treatment of the patients and absence of the little proprieties, such as protecting the patient from needless exposure and his harsh words of command when the patient showed resentment, sent a chill over many in the audience, and marred the first impressions.

Another very eminent physician gave a series of lectures with a most discordant, bronchial tone of voice. His appearance was unkempt and lacking in attractive dress to which he supplemented vague expletives, and slang words which would create a laugh. This absence of culture was so marked as to limit the value of his statements.

A wise business man said, "I always try to have a new doctor dine with me if I ever expect to employ him. I judge from his table manners what his judgment will be in professional questions. I provide a sumptuous table with wines and tobacco. If he eats abstemiously, refuses to take spirits or smoke, I reason that he has strict regard for his own health, first of all, and hence may be trusted to judge of others. If, on the contrary, he partakes of everything offered and shows untrained nutrient habits, I doubt his capacity to be relied upon as a medical adviser."

Recently a medical expert gave a most elaborate statement of the meaning of facts in a jury trial, and yet they were ignored by the verdict. One of the jurors explained that the doctor's voice, his general manners, and coarseness of utterance repelled them and cast a reflection on his honesty. Innumerable examples confirming this sort of skepticism will be recalled by every observer.

Medical students are said to be coarse and rough in their manners. Probably this was more true in the past than at present. One of the reasons most prominent is that they have no ideals that are fixed as to what the real physician should be. Their observations gather around the weakness of medical men and their disregard of the proprieties of actual life, and without training they must form some ideals or conceptions for themselves, always with the uppermost thought that the physician is anomalous and not subject to the law of culture and conventionality. Thus in a medical college, one professor illustrates the extreme styles and fashions of dress. He expresses himself in a harsh, broken voice, in a bombastic, dogmatic way. Another, while more modestly dressed, has a heavy, subdued, cringing tone of voice, uses foreign words and quotes

largely, giving the impression of superiority of knowledge. A third one has marked peculiarities of dress, speaks awkwardly, reads in a singsong way, seems out of touch with the students. A fourth may be a surgeon with a bronchial voice and an air of hurried disregard of dress, abrupt manners, and a commanding way, and so on through the various types of teachers. The student must get an impression of what a medical man should be from these.

From such sources and from his acquaintance with physicians outside, he must form a conception and utilize it in his own personality. No wonder he goes out with the vaguest knowledge of how to make the most of his own acquired abilities and how to appear to the best advantage.

A very large percentage of the teachers of the medical colleges of today are not good types of healthy men. They lack in so many ways and are so faulty in the very essentials of ideal physical culture, good manners and attractive voice that it would seem to be almost impossible for the student to get a very clear conception of what is needed most in actual practice.

Scientific training in literary colleges while broadening the student's conception of life, unless accompanied with teaching as to how it can be made most valuable and available in actual life, is of very little value. Every school should have departments of physical culture and voice training, and this should be considered of equal importance to that of any other department of medicine. Such training cannot be had in any other way, except by direct, illustrated lectures. Thus the voice, which is really one of the most melodious and perfect organs of the human body, should be trained in the best physiological and hygienic way to express the thoughts and will of the person. It should be kept in the most perfect condition and protected from every influence that will mar or destroy its power.

There is no one organ that can do more to command respect, attract attention, and influence persons in every circle of society than a well trained, highly cultivated, modulated voice. With this are associated conceptions of the proper clothing and dress that will not only protect the body, but will add to its attractiveness and give it force and power. From this there will come training of appetite, knowledge of what appetite means, and how it can be made most essential, most valuable for the development of the mind and body. From this follows training of the muscles, the skin, the poise, the general manners and capacity to adapt themselves to the varied conditions that call for ideal impressions and conclusions.

Such lectures would materialize the great mass of facts that are piled up through the four long years of study, and put them at the service of the individual, giving a new power and a new capacity which cannot come from any other source.

It is apparent to everyone that these are the neglected fields from which the bitter experience of failures and disappointments follow in the profession. Many of these facts are very strikingly illustrated in the great surgical clinics, where the most eminent men show the marvelous advances and possibilities of surgical studies. Not unfrequently these experts mar the impression they have made by their broken, harsh tones of voice and little indescribable faults of manners and conduct.

This is farther observed in the medical gatherings where papers are read and discussed. A critical layman remarked, after hearing papers read by most eminent men: "They may be very learned, but they utterly fail to apply this learning in personal manners and powers of expression, and the common cultures that we expect from leaders of the profession."

The specialist of the throat and nose seems unconscious of his failure to apply the principles of health in himself. The nerve specialist who gives minute descriptions of nerve troubles indicates the same failure to apply these principles in his manners and powers of control.

The physician who talks glibly on public health matters and shows in his bloated face and harsh voice signs of profound personal neglect of the principles he is urging, is not an unfrequent example. Almost every city and town in the country furnishes illustrations of the failure of medical men to come up to the level of the science that they are teaching, and their failure to apply it in every day life, and this is an error that should be corrected.

Graduates of the very best colleges with foreign training in addition are chagrined that their attainments are not recognized, and that they are replaced by inferior men. It is simply because they are untrained in the very essentials that would bring out the facts they possess.

The late Dr. Mott is said to have advised a physician who complained of no business and non-recognition in the community where he lived to "go home and train yourself in manners and dress and voice and living, and show them that you are a physician in all that that word means and you will have custom."

If the physician was trained to an ideal standard of personal health and attractive manners, he would be welcomed in innumerable homes, where now he is seldom employed. He would be the ideal counsellor who would bring cheer and courage and suggestion of how to live for which many persons would be glad to remunerate.

A physician on the street with an air of superiority that comes from personal culture and training would be a marked man and welcomed everywhere. If his training was right, he could not remain unknown long, either in the city or country. There would be no long waiting period for practice. He would be wanted at once, and his society would be sought for. There is no medical student or physician living who, if properly trained, with clear ideals of the position he occupies and with personal culture that would show his superiority to the common people, who would fail in the practice of medicine.

It is want of proper ideals, want of culture and profound ignorance of how to apply these principles in his own life that keeps the medical man down on a level with ordinary business men.

Shrewd quacks illustrate this in many ways. Laymen are far beyond the profession in recognizing and rewarding the men who attain this practical position which every new scientific discovery is imposing on the status of medicine.

The claim of a crowded profession is correct, and largely because the vast majority of physicians do not represent in their personal appearance, conduct and manners the priests and teachers of hygeia. They take rank in the community as common people, with all the weaknesses and peculiarities of others, padded with some special knowledge of the body and its diseases, which they attempt to apply in others and fail to use themselves.

The times call for culture of a higher type, for chairs in colleges that shall teach these very essentials and furnish the key to unlock the great capacities and powers of each individual, and make him available for the larger field of medicine that is coming.

This is the demand of the times, and the call that is felt in every town and city in the country.

DEAFNESS FOLLOWING MUMPS.

WITH THE REPORT OF A CASE.

By JOSEPH WEINSTEIN, M.D.,

NEW YORK.

In view of the fact that so few cases of this interesting condition have been reported recently in medical literature, the writer believes the following case which has come under his observation will be of interest to the profession:

J. J., male, 8 years of age. Perfectly well two weeks ago. Hearing perfect. Attended school, making good progress. Developed mumps two weeks ago, and left parotid appearing more swollen than the right. Heard normally for two days during the progress of the mumps and for two days thereafter, when he became partially deaf and said that he heard sounds as if they were very far away. At the end of five days deafness was complete. The otoscopic picture showed that both drums were normal. Functional tests elicited complete deafness. Diagnosis: Labyrinthine deafness following mumps.

The case under discussion is one of those in which the labyrinth is very probably involved in the course of an attack of mumps and in which the process is not suppurative nor due to direct extension of the inflammation from the parotid to the meatus and middle-ear, but apparently to an attack of the disease itself in the labyrinth, terminating in total deafness in one or both ears and, when occurring in infants, in deaf-mutism.

While the condition is not commonly mentioned in literature it would seem to have been frequently met with during the middle of the last century. Toynbee (1860), Dalby (1885), Hinton (1874), and Pearce (1885) having cited several cases. Mygind gives mumps as the cause of deaf-mutism in 0.3 per cent. of the cases occurring in Saxony and 0.5 per cent. in America. Bliss reported one case out of 282 cases examined by him. Hinton places mumps next to scarlet fever as an etiological factor in the impairment of hearing. Buerkner gives mumps as the cause of labyrinthine deafness in 2 per cent. of cases seen by him.

A diversity of opinion prevails among those who have studied the condition as to whether the primary lesion is in the middle-ear or the internal ear. Toynbee located the disease in the labyrinth and reported a case of hemorrhage into the labyrinth as a complication of mumps. Roosa thought that the infection traveled from the parotid gland through the external auditory canal into the tympanic cavity and thence into the labyrinth. Combeau believed it to be part of a general infection manifesting itself in many localizations. Brunner reduced the cause to an inflammatory excitation of the labyrinth, leading to rapid exudation, with no tendency to suppuration. Vogel believed the inflammation to be carried to the internal ear along the course of the facial nerve.

Thomas Barr, writing about 1889, challenges both Roosa and Vogel, saying: "The view which commends itself to my mind is that the mode of extension and the nature of the pathological process are similar to the processes in inflammation of the testicles or of the mammæ which are well-known phenomena in the case of mumps. The possibility is that the morbid poison of mumps which, according to Ollivier, is of the nature of microorganisms (cocci and bacilli) attacks, in certain cases, the labyrinthine circulation, leading to serous or hemorrhagic exudation, or to embolism of the internal auditory artery in its cochlear or vestibular branches and that in many cases the exudations are, after absorption, followed by atrophy of the nerve structures. In short, the parotitis, the orchitis, the labyrinthitis are local expressions of the same morbid condition of the blood and due to the migration of the microorganisms into these several structures."

Pollitzer (1909), citing Lannois, says: "The hypothesis that the deafness in mumps is caused by an acute exudation or metastasis in the labyrinth (similar to affections of the kidneys, ovaries, mammæ, testicles) or by an affection of the acoustic center, is without any anatomical foundation. It is most probable that this form of deafness is due to an infectious disease." Barnhill and Wales (1911) mention the condition, but make no attempt to explain it, the following quotation from their work practically covering the subject: "The tendency of mumps toward a metastatic involvement of the testes, ovaries, and breasts is well known and an explanation of the occurrence of deafness during an attack of parotitis has been made upon similar grounds. Whatever the nature of the virus of mumps may be, in the purely labyrinthine cases of deafness which result from its deposit in the inner ear, the effect seems most often to be upon the auditory nerve itself, and to finally cause more or less complete atrophy of its trunk." Ballenger (1914), speaking of aural conditions associated with "scarlet fever, measles, and kindred diseases," says: "The labyrinth is usually invaded through either the oval or round windows, as has been shown by numerous autopsies by the scar on the membrane. In some cases, however, it appears that the middle ear is not involved, the drum membrane being normal. It is probable in these cases that the infection reached the labyrinth by metastasis." Later, speaking specifically of mumps, Ballinger says: "Mumps being an infectious disease and the site of infection being automatically in close proximity to the labyrinth, the infection may be carried to it by metastasis, or it may be carried through the Glaserian fissure."

The problem still remains as to whether these cases are due to an invasion of the labyrinth by the microorganism of mumps, to metastasis similar to the mammary and testicular complications of mumps, or a toxic neuritis, the latter theory attributing the condition to a paralysis of the auditory nerve due to toxic absorption, the poisons very probably being carried into the labyrinth through the cochlear and vestibular branches of the auditory artery.

The condition has been described as a nonsuppurative process in the labyrinth occurring in the course of an attack of mumps. It is interesting to note that in no process associated with mumps is there a tendency to suppuration, an argument used in favor of the theory of invasion of the labyrinth by the microorganism of the disease itself. It manifests itself without respect to sex or age, cases occurring in patients from eleven to thirty years of age being more prevalent. The time of

onset is from four days before the appearance of the parotid swelling to fifteen days after. The onset is almost invariably rapid and accompanied by vertigo, nausea and vomiting; headache is mentioned in some cases. In a few instances the patient has become suddenly unconscious at the onset, in one case falling to the floor as if struck down. Subjective noises, sometimes very loud and violent, are usually present and the gait is always affected, becoming staggering and uncertain. The majority of cases reported have been unilateral although bilateral cases are not infrequently encountered with this condition. G. W. Boot, in a study of 51 cases, reports 32 unilateral cases and 10 bilateral. The otoscopic picture is, with very few exceptions, normal. The prognosis is bad, the condition being rarely affected favorably by treatment. Yearsley and Jollye each report a case where the patient made a complete recovery under pilocarpine treatment. Alt and Baruich report two cases, one of which recovered by an inhibition of sodium iodide and the other without treatment of any kind being directed to the auditory nerve.

E. A. Crockett (1898-1899) says that treatment has always been unsatisfactory, and expresses himself as believing that "reported cases of improvement in hearing after iodides, mercury, and pilocarpine are more likely cases of inherited or acquired syphilis, both of which frequently give a precisely similar group of symptoms." The fact that a case is rarely presented to the otologist for treatment in its earliest stages, the general practitioner usually treating it as within his province, has been a handicap to a very comprehensive study of this interesting condition. Whether cases seen by the otologist in the earliest stages might be more amenable to treatment is doubtful, the complete climax following so close upon the sudden onset, leaving little time for treatment. The chance of recovery in any pathological condition, however, is rendered more possible by its being recognized at its inception, and for this reason, as well as for the purpose of a more intelligent study of the condition, it is urged upon the general practitioner to be on the alert for an aural complication during the course of an attack of mumps, that abortive treatment may be early inaugurated.

TRANSFUSION OF BLOOD BY THE GRAVITATION METHOD.

By G. A. RUECK, M.D.,

NEW YORK.

When I started the pathological and bacteriological laboratory at St. Francis Hospital in 1911 I did the blood serum tests for syphilis according to Noguchi's method. In the spring of 1912 I compared my results of this method with those obtained by Weil's test in which very weak solutions of cobra venom are used. The first step in the preparation of the red blood cells for this cobra venom test is to use equal parts of blood and of a 2 per cent. sodium citrate solution in order to avoid coagulation of the blood. In the fall of 1912 I began to use Wassermann's original method and for each set of tests I had to get sheep's blood from a slaughter house downtown. The messenger often forgot to shake the jar as ordered and the blood in the jar coagulated. It was then difficult to get enough red blood cells in suspension for the Wassermann test. To prevent coagulation of the blood I put each time into the sterile half-pint fruit jar in which the fresh sheep's blood was to be collected about 50 c.c. of a 2 per cent. sterile sodium citrate solution. Mixed with this solution the blood did not coagulate. I have followed this method of getting sheep's blood from the slaughter house up to the present day. The blood could be kept in the ice box for 24 to 48 hours without undergoing hemolysis.

On December 12, 1913, Dr. Clarence Smith referred to me a patient who suffered with purpura hemorrhagica. I treated her by the hypodermic injection of fresh human blood serum. The bleeding stopped entirely except for a slight oozing from the mucosa of the mouth. She lived on a light diet and felt so well that she was allowed to sit up on Christmas Day, when she rashly ate a hearty meal and much canned spinach which was "not up to the mark." Next day she vomited and felt quite weak. Her anemic condition increased and upon the advice of Dr. Welch she received two blood transfusions, each of one quart of her mother's blood. The transfusions which accelerated the fatal outcome of the case were given by means of record syringes, December 31, 1913, and January 2, 1914. The technique was excellent. But I became convinced that the Lindeman method, although superior to all the older methods, is too expensive on account of the unavoidable breakage of a great number of syringes, and out of the reach of most of the patients who need a blood transfusion, because it requires quick work and a specially trained staff of 3 or 4 men in order to be successful. I decided therefore to use my old sodium citrate solution in order to prevent a rapid clotting of the blood in a flask and to introduce the human blood so treated, at my convenience, into the circulation of patients by means of the simple gravitation apparatus used for the intravenous injection of salvarsan, provided the sodium citrate would not produce any dangerous results. My experiments were the following:

Experiment I.—January 3, 1914. A gray female rabbit, weighing 2053 grams and lying head downward on an inclined warming stage devised by me was bled from the post-auricular vein, 40 c.c. of its blood being collected in 10 c.c. of normal saline solution to which 2 per cent. of sodium citrate had been added. This blood was kept in the ice box. Then the jugular vein was resected. A small cannula connected by means of rubber tubing to a glass funnel tube was introduced into the jugular vein. The rabbit was now in a horizontal position on the warming stage. Into the slightly raised funnel tube 40 c.c. of sodium citrate blood of another rabbit was poured. This second rabbit, "the donor," had been killed 48 hours ago. Its blood had been kept in the ice box 48 hours and was warmed on a water bath to 37½° C. before the transfusion was started. The rabbit died 6 days after the transfusion.

Experiment II.—January 6, 1914. A fox colored female rabbit, weighing 2038 grams was bled from the postauricular vein, 40 c.c. of its blood being collected in 10 c.c. of a normal saline solution containing 2 per cent. sodium citrate and was kept in the ice box for later use. Then the rabbit received a transfusion into the jugular vein of 40 c.c. of the sodium citrate blood obtained from rabbit No. I which had been in the ice box for 24 hours. The rabbit lived.

Experiment III.—January 7, 1914. A gray male rabbit weighing 1850 grams, was put on the warming stage, and bled from the left postauricular vein, 40 c.c. of its blood being collected in 10 c.c. of 2 per cent. sodium citrate in normal saline solution. Then the rabbit received into the right postauricular vein by means of a large syringe an injection of 30 cc. of blood obtained from rabbit II which had been kept in the ice box 18 hours. The rabbit lived. These experiments were encouraging.

To find a solution containing the smallest amount of sodium citrate necessary to prevent the blood from clotting a number of experiments were made, as a result of which it was found that a solution of 0.4 per cent. sodium chloride and 1 per cent. sodium citrate in distilled water was sufficient to prevent coagulation of the blood when 1 part of this solution was mixed with 4 parts of blood.

In case a patient would get a transfusion of 1 liter of such a blood mixture he would receive in it 200 c.c. of the sodium citrate saline solution. To determine the effect of this sodium citrate saline solution on man I injected into a patient who came to my private office 250 c.c of it intravenously, and one-half hour later I gave him an intravenous injection of salvarsan. This experiment was done May 10, 1914, and repeated May 17, 1914. The patient showed no ill effects whatsoever.

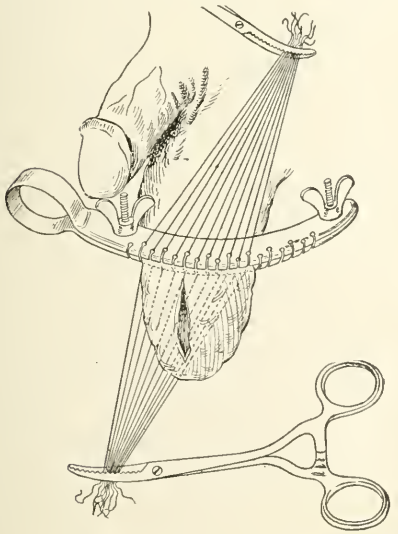
I have been waiting for a chance to try my blood transfusion method on private patients or in a hospital before I should publish it, but the fact that the MEDICAL RECORD in the number of January 23, 1915, contained an article by Dr. Richard Lewisohn, entitled "A New and Greatly Simplified Method of Blood Transfusion," leads me to publish this article now before my experiments have been completed. Since Dr. Lewisohn acknowledges that he has experimented with sodium citrate solutions only for the last few months, since my experiments are of a much older date, and since I explained my method to the staff of St. Francis Hospital and several medical friends last summer I claim to be the originator of this method of blood transfusion.

1070 TIFFANY STREET.

A NEW INCISION FOR VARICOCELE OPERATION WHEN THE SCROTUM IS TO BE AMPUTATED.

BY EDGAR G. BALLENGER, M.D.,
AND OMAR F. ELDER, M.D.,
ATLANTA, GA.

THE operation for varicocele may be done as easily



through an incision low in the scrotum as at the usual site. When the scrotum is to be amputated the incision for the varicocele may be made through the part of the scrotum which is to be removed, thereby making it unnecessary to have more than one skin incision. The same result, of course, could be obtained by amputating the scrotum first and excising the dilated veins after removing the scrotal clamp; the hemorrhage, however, is much greater and more time is required for such an operation. The danger of infection is also decidedly increased by this open operation. The illustration shows the clamp in place ready for the amputation after which the sutures may be tied.

805 HEALEY BUILDING.

Medicolegal Notes.

Malpractice—X-Ray Burn.—Action was brought to recover damages from a physician for the alleged negligent and unskillful use of an *x*-ray machine in taking pictures of the body of the plaintiff, his patient. The machine was used on four occasions, and there subsequently developed, on plaintiff's abdomen, an incurable third degree *x*-ray burn. The defense was that the plaintiff was unusually susceptible to injury from the *x*-ray. It was held not error to instruct the jury that, if the evidence showed that it was proper to use an *x*-ray machine on the plaintiff, and that when such machines are properly used burns do not necessarily result, then the fact that the plaintiff was severely burned could be considered in determining whether the defendant's use of the *x*-ray was negligent, careless, or unskillful. The defendant produced the testimony of a number of physicians, who were *x*-ray operators, which tended to show that a burn would not be expected by the use of an *x*-ray with less than two or three times the amount of exposure actually used in this case, as shown by the testimony. On the other hand, there was evidence that the use made of the *x*-ray machine and current would be expected in ordinary cases to inflict the burn which the plaintiff suffered. Upon such conflicting evidence it was held that it was the special province of the jury (which had found for the plaintiff) to determine the fact. This was a question of science in which the average juryman has no special knowledge to enable him to test the credibility and accuracy of testimony; still it did not follow that the mere number of witnesses on either side determined the preponderance of the evidence, but the general rule must apply that where the jury determined the weight of conflicting evidence, and the trial court approved the verdict and rendered judgment thereon, the Supreme Court will not reverse the judgment, even though it might appear to it that the preponderance was on the other side.—George V. Shannon, Kansas Supreme Court, 142 Pac. 967.

Sufficient Statement of Claim for Physician's Services.—In an action by a physician to recover for professional services a statement of claim was held to be sufficient which averred that between June 2, 1907, and July 24, 1911, at the special instance and request of the defendant, he rendered her certain services as a physician at the times and in the amount of $303, as shown by a true and correct copy of his book of original entry; that in payment thereof he had received from the defendant the sum of $36, leaving a balance of $267; that the charges were reasonable and proper, and the copy of the plaintiff's book of account attached showed the number and respective dates of the plaintiff's professional visits and the sum charged for each.—Paist vs. Spittall, 36 Pa. Superior Ct., 408.

Irregular Visits for Prolonged Period, When a Preferred Claim.—A claim for irregular visits to a decedent by a physician for a period of three years during a progressive disease terminating fatally will, it is held, be allowed as a preferred claim under Section 21 of the Pennsylvania Act of February, 1834, for "medical attendance during the last illness."—Roop's Estate, 22 Pa. Dist. 484.

Opinion Evidence as to Permanency of Injury.—In an action for personal injuries, a physician or surgeon may state his opinion whether the present physical conditions of the plaintiff are apt to be permanent and, if any improvement seems probable, what are the chances for a complete recovery.—Ellis vs. Chicago Railways Co., 187 Ill. App. 461.

THE FIGHT AGAINST TUBERCULOSIS.

IN a recent issue of the MEDICAL RECORD, Dr. Edward S. McSweeny, writing on the subject of institutional care of tuberculous patients, made the broad statement that the amount of money expended in this way is out of all proportion to the returns, and it cannot be gainsaid that the decline in the death rate from tuberculosis is not nearly so rapid as the increase in the money spent to combat the disease. The reason for this is twofold. In the first place, part of the difficulty is one inherent in every problem of a diminishing death rate and as such cannot be entirely eliminated by any efforts of our own. The second difficulty results from our inability to realize that the problem of prevention has now entered upon its second phase, and requires the application of new principles for its solution. The difficulty inherent in reducing death rates from any cause is one that is not entirely appreciated except by those who have made a special study of vital statistics, and even they are unable to explain it in terms entirely comprehensible to the ordinary mind. In essence it consists in the fact that the nearer the death rate from a given disease reaches the vanishing point the slower is its approach to that point. At first the decrease may assume the geometrical ratio, then become arithmetical, and finally proced by slow and irregular steps to the final goal of complete elimination.

The reason for this slow progress toward the end is well stated by Hoffman when he says, "the residuary obstacles to be overcome are decidedly more resistant to the ordinary methods of disease elimination than the more obvious and general causes chiefly responsible for the excess in the death rate of the past." Applying this principle to the problem of tuberculosis, we see at once that the greatest single influence in the spread of this disease, namely, contagion through ignorance of mode of spread, has been practically eliminated. It was in 1882 that Koch discovered the tubercle bacillus, and the contagiousness of the disease was definitely established. Before that year the decline in the death rate had been irregular and not very persistently downward. Thus, if we take the cities of New York, Boston, and Philadelphia as examples, we find that the mortality from tuberculosis (illustrated by Hoffman in his combined chart of these three cities) stuck closely to 375 per 100,000 population for the fifty years preceding 1885. Then it dropped rapidly, reaching the 225 mark in less than ten years. It is certainly significant that this extremely rapid drop corresponds so exactly with the period when the contagiousness of the disease was definitely established and intelligent people began to use ordinary care in their daily contact with consumptives. Massive foci of infection were beginning to be removed by the mere dissemination of the news that consumptives should sleep alone and not spit indiscriminately. Since 1895 the death rate has still persistently tended downward, though at a much slower pace, having fallen to 147 per 100,000 in 1913. This is primarily because the residual obstacles to be removed are incapable of removal in the way we are attempting the task. Sticking to the main fact that the disease is contagious we forget that we have already accomplished nearly all that can be expected in the way of eliminating massive foci of infection and that the smaller foci cannot be attacked in the same way, because that would involve an entire reconstruction of society.

This brings us to the gist of McSweeny's argument that we not only must recognize the difference between tuberculous infection and tuberculous disease, but must also classify our tuberculous disease patients with reference to their social strata. He points out the fact that an alcoholic tuberculous patient is primarily an alcoholic, and that a vagabond tuberculous patient is primarily a tramp. It is plain that vagabonds and drunkards cannot be expected to be trained into careful, conscientious invalids, and must ever remain a source of danger to the community unless they receive the treatment appropriate for their underlying social delinquency rather than their superimposed disease. It is not fair to the careful, self-respecting consumptive to segregate him in company with this class of social delinquents.

When we boil down the arguments of Hoffman, McSweeny, and all other careful investigators in this field of the further prevention of tuberculosis, we are struck with the fact that the problem has now entered upon its second phase. The first one, that of education, has apparently reached all classes of society which it is capable of reaching. Intellectually and morally normal men or women seldom succumb to the ravages of this disease, provided they are in a financially fit condition to carry out the necessary hygienic regime. The diminution in the death rate so far noted is chiefly, we believe, a diminution among persons in the middle and upper walks of the social strata. The lower or submerged tenth has not been reached. Neither can it be reached by the methods applicable to those of normal intelligence, adequate means, and correct personal habits. The second phase of the problem is squarely upon us, and that is a recognition of the fact that further reduction in the death rate cannot be expected until the problem of tuberculosis is considered as inseparable from the problems of poverty and social delinquency. These are the residuary obstacles which must be overcome before the $20,700,000 spent annually in the antituberculosis campaign can be expected to bring adequate returns.

THE PHTHALEIN TEST FROM THE VIEWPOINT OF THE ABDOMINAL SURGEON.

A METHOD which will accurately determine the functional capacity of the kidneys—one which, applied before operation, will allow one to know with approximate exactness how much deviation from the normal is to be expected after operation—has long been awaited, and is still hopefully looked forward to. Cryoscopy, Bouchard's method of determining the toxicity of the urine, Albarran's method of experimental polyuria, Kutner's methylene blue test, Voelcker and Joseph's indigo-carmine test, the phloridzin method of Casper and Richter, Ambard's method of correlating the amount of urea in the blood and in the urine (Ambard's coefficient), the phenolsulphonephthalein test of Geraghty and Rowntree—the development of these and many other less important tests has come from the demand, particularly on the part of the surgeon, for such knowledge of the actual functional worth of a kidney or kidneys as will allow an intelligent estimate to be made as to what may be expected of the other kidney in contemplated nephrectomy, or of both kidneys when other serious operations are under consideration. Of all these the phthalein test has perhaps come the nearest to fulfilling our expectations, and yet this also falls far short of the hoped for ideal. It was at first enthusiastically taken up by genitourinary surgeons, but they soon found that blind dependence upon its accuracy often resulted disastrously; and that while a valuable aid, it could not be the sole criterion as to the functional worth of the kidneys, but should be supplemented by the use of other methods, the final decision depending upon consideration of all evidence available in the individual case.

One question that has never been decided is the minimum two-hour percentage output with which it might be considered safe to do a major operation. Rowntree himself, in answer to this question, would only say "the greater the output the less the risk." To decide this point, if possible, and also to determine if the test would be of value to the surgeon in his routine work, Stephen E. Tracy (*Surg., Gyn. and Obst.*, Dec., 1914) employed the test in about 300 cases, taking them as they came, with absolutely no selection. In the selection of cases for operation he paid no attention to the functional test reports but decided upon the basis of other data previously used. This paper is based on observations of the first 100 cases, on which 120 tests were made. The dye was injected deep in the lumbar muscles and appeared in the urine in from five to forty-two minutes, the average being ten minutes and eighteen seconds. The total output (for two hours) varied from 21 to 96.5 per cent. The average output for the first hour was 34.27 per cent., for the second 20.83 per cent., and for the two hours 55.1 per cent. In 91.7 per cent. of the tests the output was greater in the first hour; in 8.3 per cent. in the second hour. In 20 per cent. of the tests there was not over 4 per cent. difference between the output in the first and second hours. Five cases with the lowest output in the series (21 to 27.5 per cent.) were considered good surgical risks, were subjected to major operations, one of which was a nephrectomy, and had a normal convalescence. Other cases with a much higher phthalein output died from uremia from five days to something under two months after operation. The output in four of these cases was, respectively, 53, 55, 72, and 87 per cent. In another case in which it was known that the kidneys were not normal the phthalein output was 90 per cent.

Tracy's conclusions are: "It does not seem possible to work out the minimum percentage phthalein output with which it will be safe to undertake surgical operations, nor is it possible from the phthalein test to determine what cases should or should not be subjected to operation. I believe it will never be possible to determine this point by any laboratory test, as the functional activity of the kidney varies under numerous circumstances and at different times. In determining whether or not a patient should be subjected to operation, the history, clinical symptoms and physical examination are of much greater value than any renal functional test yet devised. The phthalein test used in conjunction with the clinical symptoms, history and physical examination is of value. A small percentage output should put the surgeon on his guard and cause him to study the patient most carefully before undertaking an operation. The phthalein test should be used only as one of the many methods of investigation in ascertaining the condition of the patient." These conclusions correspond with those already arrived at by the genitourinary surgeons and not at all with the more sanguine remark of one of the originators of the test, Rowntree, that the greater the output the less the risk. There is no denying the fact that it has a certain value; but it is as a link in the chain of evidence and not as the court of last resort when the functional value of the kidney is under adjudication.

THE ETIOLOGY OF EXOPHTHALMIC GOITER.

MEDICINE offers many attractive fields for speculation, but perhaps none more attractive and surely none more exploited during recent years than the field of the internal secretions. So many plausible theories that are impossible of proof can be advanced that starting from any point in the periphery of this field a logical line of reasoning will carry the theorist straight to the heart of the problem. In fact the test of therapy is the only "acid test" we have for most of these alluring ideas.

A speculative article on Exophthalmic Goiter has recently appeared from the pen of Leonard Williams (*Practitioner* 1915, xciv, 94). He deplores the old name of exophthalmic goiter and with well recognized reasons, but views the newer term of hyperthyroidism as a positive catastrophe. So many cases of this disease exhibit a mixture of hypo- and hyper-thyroidism that, in his opinion, it is unwise to limit the conception of the disease by a narrow terminology. In spite of the obvious objections to eponymic nomenclature, Williams favors the retention of the term Graves' disease as being most suitable until our knowledge is broader on this subject. In many patients he has noted

evidence which points to the derangement of some of the other endocrinic glands. He has seen many of these patients whose eyes slant outward and upward instead of downward, the celestial angle. This is a common finding in Mongolian idiocy and has been considered as one of the stigmata of that disease. He then goes on to say that the victims of Graves' disease are, as a rule, badly balanced or, in other words, degenerate to a greater or lesser degree, and suggests that exophthalmic goiter bears the same relation to mongolism that myxedema does to cretinism. "The one is the delayed, adult, and incomplete manifestation of an intrauterine fault of which the other is an immediate and complete example." The lack of striking resemblance may be analogous to the dissimilarity existing between gigantism and acromegaly. The peculiarity in the development of the bones forming the orbit which is noticeable in Graves' disease suggests that the pituitary plays an important part, while the facial expression of "fright and flight" and the pigmentation of the skin which is rarely absent from complete Graves' disease, indicates the involvement of the suprarenal gland.

Unfortunately all this attractive speculation fails to lead to an equally attractive method of therapy. The subject of internal secretions is in such an unsatisfactory condition and there is such a deplorable lack of competent tests for the function of these mysterious glands that it is impossible to draw reliable conclusions. Williams thinks that the best plan is still to treat the patient and not the disease and emphasizes the difficulties of such a scheme. Marriage is inadvisable "for not only do their vagaries impair their husband's social efficiency, but it is very doubtful whether they are capable of bearing altogether satisfactory children." He does not discuss the infectious theory of the disease.

Such mental gymnastics as these might seem to lead nowhere, and yet it is only by continued exercise that our organs are kept fit and it is more than probable that when the light comes it will be seen first by some worker who is fond of speculation, the happy possessor of a constructive imagination.

Health of the Allied Armies.

It appears that so far the armies in the western zone of fighting have been comparatively free from epidemic disease. Typhoid fever, which generally occurs among masses of men gathered together under conditions peculiar to warfare, according to reports, has not been present on a wide scale. The Belgian troops stationed in and about Calais are said to have suffered to a considerable extent from the disease, but the British army up to the present time has been singularly free from it. *The Lancet* in its Annus Medicus published December 26, 1914, attributes this freedom largely to the action taken to obtain systematic inoculation of the soldiers with antityphoid vaccine. Cholera has been reported to be somewhat widespread among the armies in South Poland and Galicia, but no authentic news has been received with regard to its presence in the West. There has been no notification of smallpox or of any severe prevalence of dysentery in the western field of operations. On the whole, the situation, judging from the somewhat meager reports which have come to hand, is from the health point of view of the allied armies satisfactory. At any rate, it would seem probable that the occurrence and spread of typhoid fever have been checked. This result should augur well for the future, since the conditions of warfare which are going on in the West have not been of such a nature as particularly to favor the prevention of epidemic disease.

Glue in the Prophylaxis and Treatment of Frost Bites.

This old remedy has been revived in the present war, melted carpenter's glue being poured upon the feet, with special reference to the toes. The dried glue forms a superior nonconductor and the soldiers thus provided are able to march for days without the development of frost bite. At a recent meeting of the K. K. Medizinische Gesellschaft zu Wien (*Münchener medizinische Wochenschrift*, January 5) Pribram states that glue may be employed in treating frost bites. Should the feet freeze as a result of unusually severe or prolonged exposure they should be slowly thawed out by massage, a warm bath being next used to remove the dried glue, after which more warm glue is added. The author prefers personally to apply the prophylactic glue upon one side of a bandage as the latter is being applied to the foot. If in spite of all the foot freezes the massage is performed with the dressing undisturbed. Soaking the foot in warm water facilitates the removal of the old dressing which is then replaced with a fresh one.

News of the Week.

For the Relief of Belgian Physicians.—The report of the Treasurer of the Committee of American Physicians for the Aid of the Belgian Profession, for the week ending February 20, 1915, announces the following contributions:

Dr. Sylvester McNamara, Brooklyn, N. Y.	$5.00
Dr. J. Watanabe, Seattle, Wash.	5.00
Anonymous—B., Pittsburgh, Pa.	30.00
The Erie County Medical Society, Erie, Pa.	25.00
Dr. Hugh Cabot, Boston, Mass.	25.00
Dr. E. Evans, La Crosse, Wis.	10.00
Dr. W. J. Herrington, Bad Axe, Mich.	10.00
Otero County Medical Society, La Junta, Colo.	25.00
Vermilion County Medical Society, Danville, Ill.	25.00
Dr. Eva Charlotte Reid, San Francisco, Cal.	5.00
Dr. Howard Carter, Webster Groves, Mo.	5.00
Dr. G. H. Torney, Brookline, Mass.	5.00
Dr. John B. Murphy, Chicago, Ill.	100.00
Dr. D. E. McGillivray, Fort Angeles, Wash.	5.00
Dr. Charles N. Spratt, Minneapolis, Minn.	100.00
Dr. J. M. Thorne, Pittsburgh, Pa.	5.00
Westerly Physician's Association, Westerly, R. I.	10.00
Dr. J. F. Long, Chicago, Ill.	1.00
Dr. Roy Sexton, Streator, Ill.	5.00
Dr. D. E. Cornwall, St. Maries, Idaho	5.00
Aesculapian Club of Buffalo, Buffalo, N. Y.	25.00
Pocatello Medical Society, Pocatello, Idaho	10.00
Dr. A. R. Thomas, West Eaton, N. Y.	5.00
Receipts for week ending Feb. 20	$446.00
Previously reported receipts	3,133.00
Total receipts	$3,579.00
Previously reported disbursements	$3,135.00
Disbursements week ending Feb. 20, 200 boxes food at $2.20 per box	440.00
Total disbursements	$3,575.00
Balance	$4.00

F. F. Simpson, M.D., Treasurer.

The American Hospital in Paris.—Dr. George W. Crile of Cleveland, who returned to this country last Saturday after a stay of six weeks in Paris at the head of a division of the American Ambulance Hospital, is quoted as saying: "From my own observation and from talks with military and pro-

fessional authorities I have no hesitation in saying that the American Ambulance is the finest hospital produced by the war, and this is the unanimous opinion of the authorities with whom I talked. The hospital is known throughout Europe and the great work that is being done there is widely recognized." A meeting of the executive committee of the hospital was held in this city on Tuesday of last week at which it was stated that the total amount of money received thus far has been about $140,000, of which $120,000 was contributed by Americans in Europe. The average number of patients in the hospital is 390 and the average cost of each patient during the months of November, December, and January was 7.88 francs or $1.51 a day. This amount includes all expenses for food, for patients and helpers; heating, lighting, service, drugs, and even for the hospital's automobile trucks. The average daily cost of food for patients and helpers is 2.66 francs or about 50 cents. The hospital has now nearly ninety automobile ambulances in service, the great majority at the front, and this important branch of the work is being extended. The hospital records show a mortality rate of only 8 per cent., although some of the most severely wounded are sent there for treatment.

The American Red Cross sent Dr. Karl B. Downer of Lansing, Mich., to Servia last week to join the Red Cross staff already at work there, and on Saturday it despatched ten additional nurses to join the Red Cross units in France. Dr. Albert Samuel Cooke of Brooklyn, who was in the Servian hospital corps at Valemevo, died there on February 16. He was a graduate of the College of Physicians and Surgeons of this city in the class of 1903.

Typhus Fever in Austria.—A despatch from Berne states that the epidemic of typhus fever is spreading in Vienna, 346 new cases being reported during the week ending February 13. Almost daily a death is reported either of a doctor who attended typhus patients or of a priest who administered extreme unction.

Plague in Havana.—It is stated that the plague has reappeared in Havana, three new cases and two deaths being reported during the week ending February 13.

New York's Death Rate.—During the first seven weeks of this year the death rate in this city was 13.92 per thousand of population as compared with 14.59 per thousand during the same period in 1914.

Suicides.—The U. S. Census Bureau reports that there were 9,988 suicides in the registration area in 1913, the rate being 15.3 per 100,000 population, a slight decrease as compared with 1912, when the rate was 16.

Physicians Drafted in Austria.—A despatch from Rome states that all physicians in Vienna who are under 50 years of age have been ordered by an imperial decree to join the army medical corps.

Scarcity of Women Physicians in England.—According to the warden of the London School of Medicine for Women the demand for women doctors in England far exceeds the supply. In the *British Medical Journal* there appeared recently forty-two advertisements of posts for which medical women would be accepted, and no reply was received.

A Last Warning.—Our readers are warned that the Harrison antinarcotic law goes into effect on March 1, after which it will be unlawful for any physician who has not registered his name and address with the collector of internal revenue of his district and paid the special tax of one dollar a year (the first payment to June 1, the end of the fiscal year, will be 34 cents) to dispense or have in his possession any opium or coca leaves or any derivative or preparation made from them. The physician must also prepare and keep on file an inventory of all such drugs in his possession on March 1. "No special form of inventory is here required, but the inventory made must fully and clearly set forth the quantity of each kind of such drugs, preparations or remedies so held, and must be verified by oath not later than the 5th day of March, 1915." Any unfortunate doctor who fails to comply with all the provisions of this law will be liable to a fine of not over $2,000 or imprisonment for not more than five years, or both, at the discretion of the court.

Physician Arrested for Selling Morphine.—A doctor in Washington, whose two years' jail sentence was commuted to a fine by President Wilson last July after the Court of Appeals sustained his conviction for sending through the mails an offer to perform an illegal operation, was arrested again recently charged with violation of the pharmacy law in selling morphine. The man is the son-in-law of a Senator of prominence in his party.

Overcrowding of the State Hospitals.—The annual report of the New York State Charities Aid Association calls attention to the fact that the State hospitals for the insane are so overcrowded that the health and chances of recovery of the patients are endangered, and makes a plea for the immediate construction of three additional hospitals. The fourteen hospitals in the State now hold 33,358 patients, although they were built to hold only 27,463. The total overcrowding is 5,895, an average of 21.4 per cent., and the Manhattan Hospital, on Ward's Island, has 1,408 more inmates than it should have, an excess of 39 per cent.

Consolidation of Hospital Journals.—*The International Hospital Record* which has been published for eighteen years in Detroit, has been purchased by the *Modern Hospital* Publishing Company of St. Louis and Chicago and will be merged with the latter journal beginning with the March issue.

Hospital News.—The Board of Managers of the Beth Israel Hospital of New York announce that plans are now ready for the erection of a new building in Livingston Place. The new hospital will be from twelve to fifteen stories high and will provide accommodations for 500 patients. During 1914 the hospital treated 47,977 persons, 42,956 of whom were out-patients.

The new memorial hospital, erected at a cost of $40,000, was opened with appropriate ceremonies at Cedar Falls, Iowa, on February 1.

The Montreal Foundling and Baby Hospital was formally opened on January 30. The building is a three-story and basement fireproof structure with accommodations for 120 beds. In the basement is a central milk station from which milk will be supplied to all the city milk stations.

The Zurbrugg Memorial Hospital at Riverside, N. J., was formally opened on February 12. The present building, it is announced, is only the beginning of an enterprise planned by the late T. Zurbrugg, the benefactor of the Hospital. It has accommodations for twelve patients and is provided with an isolation department for contagious diseases, but it is later on to be converted into a nurses' home and to be replaced by a much more commodious structure.

The New York State Hospital Commission has

asked for larger appropriations this year, so that some much needed buildings can be constructed. For the last fifteen years an average of $800,000 a year had been appropriated for construction work, but last year it got nothing and has been forced to cut $200,000 out of the maintenance of the institutions. There are more than 35,000 insane persons in the State institutions which are fitted to house only 30,000.

The British Medical Association will hold no scientific meeting this year, although the statutory annual general meeting and the meeting of the Representative Body will be held as usual. The meeting was to have been held in Cambridge, and it is hoped that events will permit the invitation to meet in that place to be repeated in 1916.

The Missouri Valley Medical Society will hold its spring meeting at Omaha on March 25 and 26, under the presidency of Dr. Granville N. Ryan of Des Moines. The oration in surgery, to be delivered by Dr. F. H. Albee of New York, will be entitled "The Future of the Bone Graft in Surgery." An oration in medicine, entitled "An Experimental Study of Cardiac Overstrain" will be delivered by Dr. C. S. Williamson of Chicago. The secretary of the society is Dr. Charles Wood Fassett of St. Joseph, Mo.

Compulsory Twilight Sleep.—A cheerful idiot, signing himself "Ex-Medicus" (a fortunate thing for the community that he is an *ex*), writes to the *New York Times* suggesting the passage of a law defining the neglect to induce scopolamine-morphine anesthesia in a case of labor as malpractice. He says that this procedure "has been proved to be a success at least in 80 per cent. of the cases where it was employed, and as there are yet no means of determining when it will or will not succeed, it therefore should be tried in all." The most enthusiastic advocates of twilight sleep admit that the method is contraindicated or even dangerous in a certain proportion of cases, but this cautious ex-practitioner would subject all women in childbirth to scopolamine-morphine injections at the hands of experts and inexperts, physicians or midwives, and if the mothers or the babies die, well, they would probably have died anyway, for he says, "the statistics of over 10,000 cases give no greater proportion of unfavorable results than in cases of labor treated in the 'good old-fashioned way.'"

Absinthe Banned.—France has passed a law forbidding the manufacture, sale, or export of absinthe. The defenders in the Chamber of Deputies of the use of absinthe urged that the export of the liquor be permitted and that the suppression of its sale in France be limited to the continuance of the war, but both suggestions were voted down promptly and by a large majority.

Dogs Barred from Food Shops.—The New York City Department of Health has ordered printed signs to be posted in all stores where groceries, meats, fruit, and other foods are displayed for sale, directing attention to the ordinance forbidding the bringing of dogs into such places.

Revoked a Physician's License.—The Ohio State Board of Medical Registration recently revoked the license of a Cincinnati practitioner because of an advertisement he had inserted in the newspapers in which it was alleged he guaranteed to cure cases of tuberculosis inside of 36 days at a charge of $150 for the well-to-do, or a dollar a day for the poor.

Period of Quarantine in Cases of Scarlet Fever.—In accordance with the effort now making to bring the public health regulations and laws in this city into conformity with those of the State Department of Health, the quarantine period in cases of scarlet fever occurring in New York City has been fixed at "thirty days and until discharges have ceased and the disinfection of the person has been carried out," instead of the thirty-five-day period of quarantine previously enforced.

Dr. George E. Ebright of San Francisco has been appointed president of the California State Board of Health to succeed Dr. Martin Regensburger whose term of office has expired.

Dr. Ludwig Loeb has been elected medical director of the Jewish Maternity Hospital of Philadelphia and of the Jewish Seaside Home for Women at Atlantic City, in succession to the late Dr. Isaac Leopold.

Dr. Aaron Brav has been elected ophthalmologist to the Jewish Hospital, in succession to Dr. Isaac Leopold deceased.

Dr. Eduard Jacobi, professor of diseases of the skin and genitourinary organs in the University of Freiburg, died January 9 of pneumonia. He was born January 26, 1862, and was well known to American practitioners through his "Dermochromes" and "Ikonographia Dermatologica" which were republished here with English text. At the period of his death he was with the Upper Rheinish army, in charge of an organized attempt to prevent venereal infection among the troops.

Obituary Notes.—Dr. C. H. VIEHE of Evansville, Ind., a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1876, and a member of the Indiana State Medical Association and the Vanderburg County Medical Society, died at his home on February 1, aged 78 years.

Dr. PATRICK H. CANEY of Vincennes, Ind., a graduate of the Kentucky School of Medicine, Louisville, in 1892, a member of the American Medical Association, the Indiana State Medical Association, and the Knox County Medical Society, and formerly secretary and a member of the Vincennes Board of Health and coroner of Knox County, died at his home from lobar pneumonia, on January 30, aged 52 years.

Dr. GEORGE B. LITTLE of Burlington, Ia., a graduate of the Rush Medical College, Chicago, in 1873, and a member of the Iowa State and Boone County Medical Societies, died at his home, from paralysis, on January 31, aged 63 years.

Dr. CHARLES F. ADDIS of Rineyville, Ky., a graduate of the Kentucky University Medical Department, Louisville, in 1906, died recently at his home, aged 36 years.

Dr. WILLIAM DUGAN KELLY of Boston, a graduate of the Harvard University Medical School in 1903, a member of the staff of Mount Sinai Hospital, Boston, physician to the Sunnyside Day Nursery, and a member of the Massachusetts Medical Society, the Boston Medical Society, and the New England Pediatric Society, died at the Carney Hospital from blood poisoning following tonsillitis, on February 8, aged 35 years.

Dr. EDMUND A. CHAPOTON of Detroit, Mich., a graduate of the Detroit Medical College in 1875, clinical professor of the practice of medicine in the Detroit College of Medicine, attending physician to St. Mary's Hospital, a former member of the Detroit Board of Health, and a member of the American Medical Association and the Michigan State and Wayne County Medical Societies, died at his home suddenly on February 6, aged 62 years.

Dr. Caleb Winfrey of Kansas City, Mo., a graduate of the Washington University Medical School, St. Louis, in 1847, died at St. Joseph's Hospital, from uremic poisoning, on January 30, aged 92 years.

Dr. Horace M. Julian of St. Louis, Mo., a graduate of the University of Maryland School of Medicine, Baltimore, in 1885, died at his home on January 30, aged 53 years.

Dr. Frank C. Manchester of Grafton, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1885, died at his home, from influenza, after a short illness, on January 28, aged 53 years.

Dr. Truman Coates of Oxford, Pa., a graduate of the Cleveland, O., College of Physicians and Surgeons, in 1888, died at the Polyclinic Hospital, Philadelphia, on February 1, aged 63 years.

Dr. George Howard Hungerford of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, in 1909, a medical examiner for the Pennsylvania Railroad, died at the German Hospital, Philadelphia, following an operation for intestinal disease, on February 1, aged 29 years.

Dr. Herman T. J. Howe of Waitsfield, Vt., a graduate of the University of Vermont College of Medicine, Burlington, in 1877, died at his home, after a long illness, on January 22, aged 64 years.

Dr. John J. McFadden died at Philadelphia on February 12 at the age of 56 years. He was graduated from Jefferson Medical College in the class of 1888.

Dr. Samuel Augustus Fisk of Brimfield, Mass., a graduate of the Harvard University Medical School in 1880, and a member of the American Medical Association and the Colorado State Medical Society, died in Boston, on January 18, aged 58 years.

Dr. Lewis C. Hammond of Clarkston, Mich., a graduate of the Michigan College of Medicine, Detroit, in 1883, and a member of the Michigan State and Oakland County Medical Societies, died suddenly from heart disease, on January 12. He was for many years health officer of Bay City, Mich.

Dr. Thomas Hutchinson Ashton of Lincoln, Neb., a graduate of the Medical Department of the University of Nashville, Tenn., in 1865, and a surgeon in the United States Army during the Civil War, died at his home on December 20, aged 73 years.

Dr. William Grant Moore of St. Louis, Mo., a graduate of the Jefferson Medical College, Philadelphia, in 1875, professor of medicine in the St. Louis University School of Medicine, a member of the American Medical Association, of which he was vice-president in 1910, the Missouri State Medical Association, of which he was at one time president, and the St. Louis Medical Society, died at his home from pneumonia, after a short illness, on January 28, aged 61 years.

Dr. Ernest W. Russell of Lewiston, Me., a graduate of the University of Vermont College of Medicine, Burlington, in 1879, and a member of the American Medical Association, the Maine Medical Association, and the Androscoggin County Medical Society died at his home from cerebral hemorrhage, on January 29, aged 56 years.

Dr. Charles W. Johnson of Litchfield, Ill., a graduate of the Jefferson Medical College, Philadelphia, in 1872, and a member of the American Medical Association, and the Illinois State and Montgomery County Medical Societies, died at his home on January 23, aged 67 years.

Correspondence.

UNAUTHORIZED AND PREMATURE PUBLICATIONS IN THE LAY PRESS.

To the Editor of the Medical Record:

Sir:—In view of the statement relating to the treatment of cancer appearing in the *New York Times* of February 19, 1915, will you be kind enough to give a prominent place to the following communication.

On December 15, 1914, the trustees of the General Memorial Hospital of this city adopted the following resolution, a copy of which was sent to each of its members and to the members of its Medical Board. "At a meeting of the Board of Managers, held on December 15, 1914, the action of the Medical Board in appointing an Editorial Committee consisting of Drs. Ewing, Coley, and Weil, 'to look over and pass upon all articles to be published from the wards of the hospital (research and clinical),' was, upon recommendation of the Executive Committee, approved, and it was directed that formal notice be sent to all members of the Board of Managers and the Consulting Staff, informing them of the existence and duties of the Editorial Committee. The appointment of the Editorial Committee was in line with the policy adopted at a meeting of the Executive Committee held May 3, 1914, when the following resolutions were adopted: 'No publication relating to the Medical, Surgical, or Research work done in the hospital shall be made public without the approval and consent of the Medical Board.'"

This resolution is presented here as a reply to the statement above mentioned dealing with the investigation of cancer as carried on at the General Memorial Hospital. An inquiry shows that neither the Medical Board nor any member thereof has made the statements contained in the article. As Dean of the Medical College of Cornell University, which institution has been entrusted by the Board of Managers of the General Memorial Hospital with the investigation of cancer which is there being carried on, I must enter a denial of the claims made in this article for any of the agents presented therein. This I here do.

W. M. Polk, M.D.,
Dean.

New York,
February 20, 1915.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

X-RAYS AND MILITARY SURGERY—TELEPHONE IN DETECTION AND REMOVAL OF BULLETS IN TISSUES—LANTERN SLIDES OF WOUNDS—TOXEMIA OF PREGNANCY—BLACK APPENDIX.

London, February 5, 1915.

The war in some aspect or other intrudes into every conversation, whatever the subject. In last week's meeting of the Medical Society it was prominent. Dr. Ironside Bruce exhibited an *x*-ray director which he had invented for, and read a paper showing it would be found very helpful in, finding and removing bullets and other metallic bodies from the tissues. Sir J. Mackenzie Davidson complimented Dr. Bruce and pronounced his apparatus as accurate as it was ingenious, and Mr. Donald Armour was equally complimentary as to its value and accuracy. Mr. Maynard Smith said he always used an *x*-ray screen during the extraction of foreign

bodies and he thought Dr. Bruce's plan would be a decided improvement on the ordinary method. Sir J. M. Davidson then gave an address on the Telephone Attachment in Surgery. His attention to this matter was first attracted by the attempts to locate by electricity the bullet in the body of President Garfield. Some years later (1887) he had contrived an apparatus and used it for an operation performed by Dr. Ogilvie Will at the Aberdeen Infirmary. He now uses a telephone, preferably with double receivers, connected by an elastic band, so that each ear has its receiver, thus intensifying the sound and shutting off outside sounds. A large carbon plate attached to one pole is placed on the patient's moistened skin. The other end has attached to it a bare wire (silver preferred) disinfected. This wire can be wound round any instrument or a clip can be used to connect it. Under these conditions, when the instrument is introduced into the body it will, on contact with any metal met with, give an unmistakable click carried through the telephone. A needle attached can be run down to a foreign body and kept in position as a guide. So can forceps be used as a probe and then opened to include the foreign body. Sir J. M. Davidson mentioned some cases and suggested that the surgeons should now, instead of trusting his sense of touch be guided by his ears. On the conclusion of Sir J. M. Davidson's address, Mr. Donald Armour described a case in which he had quite easily removed from the orbit by this method a bit of shrapnel 3 mm. wide, which was 12 mm. below the surface.

Afterwards Dr. Howard Humphris exhibited by lantern slides some injuries among the wounded who had reached the Third General Hospital here, *e.g.* bullets which had penetrated and remained in the tissues.

The relation of the toxemia of pregnancy to food and the digestive processes occupied the Irish Academy (obstetrical section) some weeks since. Dr. E. H. Tweedy opened the question by relating a severe case of hyperemesis cured by complete abstinence from all food and the administration of warm alkaline enemata to 4 pints in 24 hours. Some interference with the processes which normally take place between foods and their antibodies must occur and this he thought it reasonable to conclude was connected with the foreign albumin derived from chorionic villi, known to circulate in the blood. He suggested that the effort to neutralize this foreign albumin might cause a diminution in the blood of the normal food antibodies. Morning sickness was an effort to get rid of food which had not combined with its proper antibody. All food, even milk, might cause vomiting or convulsions; injurious effects were not due to irritation, nor to fermentation, but to absorption at the earliest process of digestion. Dr. FitzGibbon thought the toxins of decomposing food brought on the symptoms when superadded to the waste products of pregnancy which already fully taxed the effort to excrete them. By preventing constipation toxemia is prevented, as by purgatives it may be cured. Prof. A. Smith recognized reflex, neurotic, and toxemic cases—the last coming on after the second month. He suggested it might have a fetal origin. He would give distilled water and he condemned the use of soda bicarbonate, but would give simple enemata. Dr. Solomons found the greatest difficulty was to decide when it became necessary to induce premature labor. Dr. Madill suggested that in the later months the condition might be due to absorption from the intestines aided by excessive secretion from the ductless glands which were known to hypertrophy in pregnancy. He agreed as to the bad effect of giving food prematurely and mentioned a case in which a little milk brought on a severe attack. The president, Dr. Gibson, said most cases were hysterical and Dr. Tweedy's treatment satisfactory. He found the best results from terminating the pregnancy when the patients had no reaction towards the usual remedies. It was obvious that food was injurious in severe toxemia, though it was difficult to see why it should be the cause of the condition. Dr. Tweedy, in reply, said he had brought forward the subject to get opinions as to the exact role of food. If it could lend aid to poisoning, how much aid? He admitted hysterical cases, but the toxic effect must precede the hysterical symptoms.

Mr. W. H. Battle of St. Thomas' Hospital has drawn the attention of the surgical section of the Royal Society of Medicine to the condition he calls black, or pigmented, appendix. It is characterized by a very unusual amount of pigmentation of the mucous membrane of the appendix which he found after its removal for disease. He related four cases in the *Lancet* (July 19, 1913), and now he reports two additional ones to the society. In all six cases there was "extensive brownish-black pigmentation" —not limited to the appendix but extending an unknown distance beyond. All the patients were females with chronic constipation, in more than one reported as stasis. Microscopic examination showed a fine deposit both in and between the cells of the mucous membrane which on chemical analysis proved to be some compound of iron. Mr. Battle has little doubt that this is derived from the wheat flour and that from the iron rollers used in milling. He found these rollers are fluted and the fluting wears down rather rapidly. Grinding with iron rollers had to be given up for paints on account of brown patches appearing on walls after painting with those ground with them. The rollers wear away more quickly with wheat, which is very hard. Chemical examination of the best flour detects an abnormal quantity of iron, though it is not separable by a magnet. He suggests that constipation, said to be increased of late, may be due to the consumption of this flour, so, too, stasis and concretions. He submitted some of these to a chemist with a negative result. The quantity must be minute. The influence of roller milling in reference to appendicitis has interested him for some years and facts are accumulating to show it is a serious factor. He has little doubt that enough "iron dust" is given out to cause in some instances blackening of the living membrane over a considerable part of the large bowel, a coloring more extensive than could be produced by extravasated blood and is besides more uniformly diffused. This blackening is of course in addition to the localized ulceration of the membrane sometimes caused by the sharp particles in the iron dust resulting from the disintegration of the fluting of the rollers.

The Chemotherapy of Malta Fever. — G. Izar has found that in experimental infection of the mouse, cat, and rabbit with the *Micrococcus melitensis*, the use of ethylhydrocuprein is capable of arresting the infection in 68 per cent. of the cases provided that this drug is injected no later than the ninth day of the disease.—*Pathologica.*

2. Differential Diagnosis and Indications for Treatment of Tumors of the Neck. O. C. Smith.
3. Renal Infections. W. H. Robey, Jr.
4. A Case of Human Rabies. H. Linenthal.

1. Venereal Disease and Prostitution.—W. D. Bieberbach points out the antiquity of both venereal disease and prostitution. He believes that the German method of supervising the latter has tended materially to check the former. He advocates the system of municipal quarantine of the highly infective patients that do not submit to proper treatment. Venereal hospitals or venereal wards in connection with all general hospitals should be established in all cities, and dispensaries should be well equipped for the care of ambulatory cases.

3. Renal Infections.—W. H. Robey, Jr., states that renal infection is a disease which the general practitioner should have constantly in mind since it may be mistaken for tuberculosis, typhoid fever, malaria, appendicitis, or any other febrile disease. If the urine contains considerable pus, the diagnosis of cystitis may be made and the patient fruitlessly treated for this symptom month in and month out. Cystitis is generally a symptom, and unless the diagnosis has been confirmed by cystoscopic examination should be classed with such meaningless terms as "indigestion" and "rheumatism," and should not be accepted as a disease any more readily than pain in the abdomen, headache, or irregular pulse. Cases of pyelitis of tuberculous origin should not be allowed to continue until the bladder is involved. Renal infection must be considered in the differential diagnosis of every febrile affection. The urine may show much or little according to the degree of intrarenal pressure and drainage and the condition of the ureter, so that frequent and thorough examinations of the sediment are necessary. The two most constant signs are pus in the urine and some degree of tenderness in the kidney by bimanual palpation.

4. Human Rabies.—H. Linenthal reports a case of rabies in which the patient received a full course of intensive Pasteur treatment without developing an immunity. The treatment with quinine and urea hydrochlorate intravenously injected (as tried by Harris with success in one case) was resorted to without avail. Salvarsanized serum was used intraspinally, but with no success.

14. The Menace of Antimedical Legislation. W. J. Cruikshank.

1. The Shockless Operation.—W. F. Campbell notes that the happy results of anoci-association are nowhere demonstrated to better advantage than in abdominal operations. The complete relaxation of the abdominal wall, the painless postoperative wound, the absence of intestinal paresis and gas pains, the speedy convalescence, are the indisputable facts which attest the beneficence of the anoci method. The method takes time and careful attention to detail. It individualizes the patient; it necessitates the intelligent cooperation of every member of the hospital staff; but it pays, and the returns are shown in a marked reduction in the mortality rate and the postoperative morbidity.

4. Twilight Sleep.—J. O. Polak believes that the scopolamine-morphine analgesia is particularly indicated in nervous women of the physically unfit type in their first labor, for it is in this type of women that labor has most often, in ordinary practice, to be terminated artificially, owing to the physical exhaustion so common at the end of the first stage, before cervical dilatation is complete, or in the second stage, when no more force can be brought upon the uterus by the abdominal muscles. The usual obstetrical interference by forceps in unprepared soft parts results in a permanent morbidity and is the largest contributing cause to the collection of chronic invalids. Used in conjunction with the colpeurynter scopolamine-morphine analgesia materially shortens the dilatation stage in dry labors, when the uterine contractions are active.

5. Gynecological Operations upon the Insane.—G. Gibson reports the results in a series of cases, which results show that something may be gained by correcting pelvic conditions in women who have certain forms of insanity. This is particularly so in the case of mania depressive insanity.

8. Pelvic Abscess Following Fowler Position in Appendicitis.—By H. Beeckman Delatour. (See MEDICAL RECORD, Vol. 86, page 1029.)

9. Control of Hemorrhage in Suprapubic Prostatectomy.—R. S. Fowler recommends the following method: The tip of a tube of a suction apparatus with a direct inflow for hot solution is placed in the cavity from which the prostate has been removed. The inflow tube is connected with an irrigator containing boiling water. The sucking portion of the apparatus is connected with the vacuum bottle in which a vacuum is maintained in the usal manner by flowing water. The apparatus, before its introduction, is tested, for it is important that suction be perfect. Introduced into the cavity with the inflow tube shut off, all blood is sucked out, and while this suction is continued the boiling water is allowed to flow through the inflow tube into the cavity. The inflow is regulated so that the suction does not allow the boiling solution to come in contact with any but the raw tissues. This is readily accomplished. After two minutes' application of the boiling solution hemostasis is complete, and the surrounding parts have not been injured.

1. Specific Cause of Pyorrhea Alveolaris. — C. C. Bass and F. M. Johns conclude from their investigations that (1) Pyorrhea dentalis and alveolaris is practically a universal disease, which leads to the loss of the teeth by a long suppurating process. All people have it sooner or later. It begins in early adult life or earlier. (2) The specific cause of the disease is *Endameba buccalis* and possibly other species, which infect and destroy the peridental membrane. The pyorrhea results largely from the secondary infection. (3) The demonstrable endamebas can be destroyed by giving one-half grain of emetine hydrochloride hypodermically for three to six successive days. (4) The lesions require variable lengths of time to heal, but many could not reasonably be expected to heal in less than several weeks or months. (5) The treatment must be repeated from time to time until the lesions all heal, on account of relapse, or probably reinfection of the lesions as a result of the great prevalence of the infection. (6) Injecting ipecac or emetine into the worst lesions ought to be of service and can be carried out by patients in many instances. (7) Rinsing the mouth thoroughly with a solution of fluid extract of ipecac is believed to protect to some extent against reinfection, and actually cures the disease in its earliest stage in some instances.

2. Skin Grafts in Ambulatory Treatment of Ulcers. —J. S. Davis bases his report upon fifty cases of ulcers treated by skin grafts in the Johns Hopkins Dispensary. The grafts were kept in position by placing overlapping strips of rubber protective or a sheet of paraffin mesh, and securing this and the overlying gauze dressing with numerous strips of adhesive plaster. Over this is placed again more gauze and a snug gauze bandage and finally a muslin or crinoline bandage. Sometimes with these, thin strips of splint wood were incorporated with the dressings, so as to insure the perfect rest required, and still allow the patient to go about his daily occupation. All the grafts were autografts, small deep grafts being generally used. When placed close together sometimes the ulcers were covered with epithelium within a week. Sometimes when a partial grafting was done or when only a few of the grafts were successful, a second grafting was required. In some cases, several successive graftings were ineffective, but several of these cases were subsequently successfully grafted as hospital patients. The failures were mostly confined to the feet and legs, and no case of actual recurrence has been observed on the same site in patients successfully grafted.

8. Lymphoid Growths of the Laryngopharynx.—W. E. Casselberry states that the lymphoid follicles on the rim of the larnyx undergo an immense hyperplasia, developing into tumor-like growths which occupy the space of the laryngopharynx, being heretofore of unknown origin, and only vaguely described under the mistaken term "lymphoma." It is this tumor-like formation in the laryngopharynx which the author has found definitely in two cases, by cultural, microscopic and vaccine methods, to be of microbic origin, having found also the infiltrating type of hyperplasia at the eustachian orifice to partake of the same nature. A fair inference from these findings, considering clinical similarity, points to the hyperplasia at the other sites named as of like infective origin. Leukemia was excluded by the absence of any involvement of the lymphatic glands, and malignancy was negatived by the microscopic test which showed, in each instance, a simple hyperplasia of lymphoid tissue similar to that of the tonsils.

9. Sciatica and Appendicitis.—B. M. Randolph is convinced that the initial attack of right-sided sciatica in his patient was really an attack of acute appendicitis with peripheral pain in the sciatic nerve due to the proximity of the inflammatory foci to its fibers. From the examination of the specimen, there had evidently been an intraappendicular abscess of long standing, causing a tension in its lumen. The removal of this tension by discharge of pus and inflammatory exudates left behind very little trace of the earlier acute inflammation.

6. A Simple Method of Administering Drugs.—F. W. Tunnicliffe advocates the use of the following method which he has employed, and which is capable of wide application, particularly under war and other strenuous conditions. The drug is given in a semi-solid aromatic base and the mass is enclosed in a collapsible tube such as is generally used to contain remedies for external application. The base must be sufficiently viscid to enable a continuous semi-solid jet of substance to be exuded from the nozzle by pressure at the bottom of the tube. By varying the composition of the base in glycerine, bismuth base, agar-agar, &c., all climatic conditions can be allowed for. There are many kinds of collapsible tubes on the market; those are specially to be recommended in which the screw cap is permanently attached to the neck of the tube; in these the cap cannot be lost. With a given base the weight of a given length of jet is practically constant, and by this means an accurate dosage can be obtained. The medicinal creams which the author has had made so far all have the same dose—viz., 1 linear inch of the exuded jet. An inch can easily be measured against the last joint of the thumb, and indeed can practically always be guessed.

7. Treatment of Persistent Diphtheria Infection.—R. Tanner Hewlett reports additional cases showing the value of treating persistent diphtheria infections by means of one or more injections of diphtheria endotoxin prepared by the MacFayden method. Up to date 24 cases of persistent diphtheria infection have been treated with endotoxin. Of these cases, in 17 the bacilli disappeared within a reasonable time after the use of the endotoxin; in one the bacilli did not appear until 17 days after the last dose of endotoxin, and in 6 the treatment was unsuccessful. As regards the last named, it is noted that some of them were those first treated, and the doses were smaller than the author now employs. The treatment recommended is to give doses of .5 c.c., 1.0 c.c., and (if required) 1.5 c.c. at intervals of about seven days. In no case has any untoward effect been noticed. The endotoxin is injected into the muscle of the upper arm or back, and gives rise to some pain, tenderness, and swelling, lasting a day or two, at the site of injection, and occasionally to some malaise, rash, and rise of temperature. Thus in 75 per cent. of the cases the use of the endotoxin has been followed by the disappearance of diphtheria bacilli, and the results are such as to warrant an extended trial of the endotoxin in the treatment of these troublesome cases of persistent diphtheria infection.

6. Baths for Wounded Soldiers. R. Fortesque Fox.

3. Parenchymatous Syphilis.—F. W. Mott presents the evidence which apparently favors the view that there may be a biological difference between the spirochetes of general paralysis and tabes and those of primary syphilis. The successful innoculation experiments of Noguchi, Berger, and Steiner with a long incubation period supports this conclusion. No one has been innoculated by handling brain material of general paralysis, and the unsuccessful attempts to infect monkeys, even when the material has been obtained from the living body and immediately introduced into the body of the animal, shows that the organism has undergone a biological change.

5. The Army Rum Ration. — Sir Victor Horsley makes a vigorous protest against the recent reintroduction into the English Army of the old rum ration. He notes that the following physiological effects have been observed by military and naval officers to follow from the issue of the rum ration: (1) Decadence of morale. Causation of grousing, friction and disorder. (2) Drunkenness. Punishments. Degradations in rank. (3) Decadence of observation and judgment. Causation of errors and accidents. (4) Loss of endurance and diminution of physical vigor. Causation of fatigue, falling out, and slackness. (5) Loss of resistance to cold. Causation of chilliness, misery, and frostbite. (6) Loss of resistance to diseases (particularly those occurring under conditions of wet and cold), namely, pneumonia, dysentery, typhoid fever. (7) Loss of efficiency in shooting. (Half the rum ration causes a loss of 40 to 50 per cent. in rifle shooting. The naval rum ration causes a loss of 30 per cent. in gunnery shooting.)

6. Note on a Successful Method for the Extermination of Vermin Infesting Troops. S. Monckton Copeman.

1. Use of Ether in Surgical Therapeusis. — H. F. Waterhouse calls attention to the potency of ether in the treatment of grossly infected wounds. It is particularly valuable as an antiseptic agent, in the following three conditions: (1) Infections of the peritoneal cavity and cases in which, in the course of an abdominal operation, soiling of the peritoneum has, or may have, occurred. (2) Cases of acute arthritis proved or presumed to be secondary to a pyogenic focus existing in the body prior to the onset of the joint affection. (3) Severe, septic gunshot wounds.

2. Action of Ether on Certain Microorganisms.—W. W. C. Topley states that experiments made *in vitro* show that ether and its vapor have a definite bactericidal action, but it would be difficult to imagine anything in the nature of a complete sterilization of an infected peritoneum taking place, and both the clinical and experimental results indicate that nothing of the kind occurs. The nature of the effusions produced by the injection of ether does not lend any support to the idea that an increase in the local leucocytosis is an important factor, since the cells are always scanty. The various immune bodies which may be supposed to be present in the exudate are possibly more important, but it seems doubtful whether the ether would greatly increase the hyperemia already present in an acutely inflamed serous membrane or the amount of exudate in the corresponding serous sac. Some recent investigations carried out by Gardner have an important bearing on this subject. He examined a large number of peritoneal exudates for the presence of aggressins. He concluded that the aggressive action of such exudates increases proportionately with the multiplication and breakdown of bacteria, and suggests that such substances as ether and colloidal silver may act by killing the bacteria or inhibiting their growth, and thus lessening the output of aggressins. Possibly a large proportion of the bacteria are directly killed by the ether and its vapor, possibly also organisms which have been modified but not killed are more easily destroyed by the tissues, and it should be noted that all the evidence seems to indicate that the toxicity of the ether to he body tissue is very slight. In this way the mass of infection would be greatly reduced, and this is probably a point of no small importance. These factors, combined possibly with some stimulant action, would in many cases turn the balance in favor of the tissues and against the bacteria. Any possible action of the ether on the various remote body organs has not of course been considered.

Berliner klinische Wochenschrift.

January 11, 1915.

Sexual Life and Warfare.—Touton continues his interesting study of this subject, with special reference in this number to the present war. From 7 to 8 million men sexually mature are living the soldiers' life in time of war with all that this implies. The overwhelming majority of these men have been addicted to sexual intercourse, legal or illegal. First what becomes of the women with whom they held these relations? The reputable wives are suddenly thrown into a condition of absolute continence, which must have certain consequences which are not parallel to anything in the lives of unmarried girls, old maids, and those long widowed. But to many naturally frigid wives, abstinence is the very reverse of a hardship; and this holds true of many others worn out by too frequent childbirth or its pathological results. But wives in their thirties, when the sexual impulse is strongest, often suffer from the sudden cutting off of sexual relations, and react as neurasthenics or hysterical, irrespective of the mental state which follows the cruelties of war. In diverting themselves in time of war certain women who plunge into charitable activities, volunteer nursing, etc., wish merely to be thrown into the company of the soldiers and are then led to form relationships with them. Recently in Berlin women who were nurses or at least posed as such were found to have been infected venereally by soldiers. The author takes pains to state that this sort of argument in no wise applies to strong women with a well-developed ethical sense, and he breaks off abruptly to consider the relationship between soldiers and prostitutes. At present the female camp follower has become impossible. What then becomes of her? Naturally they emigrate to the neutral countries if they can, but it is not easy for them to obtain passports. If they stay at home their activity is greatly

restricted. Forced into other callings they are likely to become criminals. Perhaps many starve to death. The better class of women engaged in prostitution become degraded and diseased. The author has no doubt that they lead many poor but decent girls astray, despite the lack of male demand. As already stated war is to some extent an unaphrodisiac for the soldiers, for fornication usually accompanies high living and idleness. The hardships of the present war, with its trench digging and trench life, were much less in evidence in the old-time warfare. But as in old days both prolonged siege and conquest change the conditions materially, although sieges are no longer matters of waiting but of permanent offensive. Conquest of large cities as in Belgium and France floods them with soldiers who flock to the bars and amusement places. The suppressed sexual impulses are soon aroused and the men form relations with the native women and patronize the prostitutes. Meanwhile the troops who have not been called to the front lead a relatively idle life in the large cities and behave like any soldiers in time of peace. In regard to outrages or harsh treatment of the women of the conquered the author is at much pains to introduce a sadistic element to explain them. The latter is believed to be always latent in normal sexual relations. Lust is heightened if pain and humiliation can be inflicted upon the women. War calls forth the latent sadistic impulses. Sadism is less marked in women, but in warfare mutilations are practised on the invading soldiers which in times of peace would be reserved for faithless lovers. The author's only surprise is that in this immense war so few sadistic practices have come to light, and believes that good as well as bad impulses assert themselves under stress. The article will be continued.

Warfare and the Problem of Feeding the People.—Oppenheimer admits freely that immense quantities of food supplies have been cut off from Germany and cannot be made good. This privation includes fodder and fertilizer. He then proceeds to enumerate German resources which can be drawn upon from home markets and friendly contiguous countries. He calls attention to the fearful waste of food over body requirements. The actual requirement of the German people is over 56 billions of calories per annum, not including 1.6 million tons of utilizable protein. The amount actually consumed before the war, however, was far in excess of these requirements. The number of milliards of calories consumed per year was 88,649, the excess of protein over 600,000 tons, etc. A large amount of these excessive food values were imported—perhaps on an average 25 per cent. The original demand for calories can draw upon a 20 per cent. reserve, although for protein there is a deficit of about 3 per cent. of the natural demand.

Münchener medizinische Wochenschrift.

January 12, 1915.

The Possibility of the Appearance of Exotic Affections During the War.—Mayer begins with a reference to the auxiliary troops of the allies—Senegalese, Turcos, Hindoos, East Siberians and Caucasians—and the possibility of the introduction into Europe of some of the maladies of normal incidence in their countries. In Senegal these comprise tuberculosis, lepra, bubonic plague, trypanosomiasis, beriberi, craw-craw, guinea worm, filariasis, bilharziasis, ankylostomiasis, sand fleas, yellow fever. The Algerians suffer from trachoma and Malta fever. The Hindoos are liable to kala azar, the East Siberians and Caucasians to relapsing fever. More or less common in all these countries are malaria, dysentery and intestinal parasites. Taking the most serious of these affections in order, leprosy is hardly likely to be smuggled into Germany, provided all prisoners are closely examined. Bubonic plague on the contrary can readily enter ports like Marseilles through infected ship rats. The pneumonia form of plague can hardly visit Germay unless Russia is first attacked. In regard to trypanosomiasis it is enough to state that cases of imported sleeping sickness have been found among the Belgians. This affection can hardly arise *de novo* in Europe as it is spread almost wholly by native flies. The colored troops who have been made prisoners suffer alarmingly with ankylostomiasis. In theory the latter could infect Europeans through the stools but the condition is readily controlled with thymol. The dangers from bilharziasis and filariasis are largely theoretical thus far, no cases of either being cited. Since kala azar attacks Hindoo adults, cases may be present among these troops. The method of propagation has never been determined. Malta fever, common in North Africa and India, is already known in France in isolated foci. Trachoma is especially common in North Africa. In the other diseases as in those already enumerated, the dangers of importation are thus far chiefly theoretical.

Biology of and Warfare Against the Clothes Louse.—No less an authority than von Prowazek has occupied himself with this subject. Since we have no cure for the louse-borne disease exanthematous typhus, too much pains cannot be spent in ascertaining the best methods for rapid and thorough disinfection of clothes and premises as well as the person. The author found that sexually mature individuals are less resistant than the younger lice. Steam disinfection and the use of benzine are hardly practicable among troops. An ideal remedy must be handy, must not be injurious to the clothing, must not be inflammable. Hence the ethereal oils and notably oil of anise are the remedies which can fill these indications. That the oils destroy the pests slowly is not a drawback. From the very outset they attack them and interfere with all their activities. The author suggests for the destruction of the lice from 30 to 40 parts pure anise or fennel oil to 70 or 60 parts of 96 per cent alcohol. This lotion is prescribed only for surface frictions. The technique of disinfection of clothing and linen is not mentioned, etc., hence no doubt the methods already in use answer very well. No doubt the author believes that cutaneous frictions with the above lotion will paralyze the activities of the lice in the underwear and eventually destroy them.

Diagnostic Points in the Exanthemata.—U. Mariotti states that measles, scarlet fever, and variola may sometimes be confused with one another. The eruption of measles may be confluent, and the typical eruption of smallpox may be preceded by a scarlatiniform rash. Of the three diseases scarlet fever has the shortest period of invasion. In this disease the eruption begins on the trunk or extremities and extends to the face and neck. In measles and scarlet fever the eruption begins on the face and neck and extends to the trunk and extremities. In variola the temperature decreases with the development of the eruption, while in scarlet fever the maximum of temperature corresponds to the maximum of the eruption. In measles there is no such close connection between the temperature and the rash. In some cases in which the temperature has been high from the beginning of the invasion, it may recede upon or even before the appearance of the rash, whereas in other cases the temperature continues to rise with the development of the rash.—*Il Policlinico.*

Insurance Medicine.

Can Insurance Experience Be Applied to Lengthen Life?—Arthur Hunter, Chairman Central Bureau Medico-Actuarial Mortality Investigation, and Actuary New York Life Insurance Company, answers this question in the affirmative. Forty-three life insurance companies in the United States and Canada agreed in 1909 to prepare their collective experience on many different classes of insured. The investigation was put into the hands of the Actuarial Society of America and the Association of Life Insurance Medical Directors. Records were supplied on about 2,000,000 lives, covering a period of twenty-five years. The object was to determine from past experience the types of lives among which the companies had a higher mortality than the average. It has taken the Central Bureau about three and a half years of continuous labor to produce results. The insured were divided into classes, of which the following are the chief groups: (1) Those who were in occupations involving hazard; (2) those who had a family history of consumption; (3) those who had a defect in their personal history, as appendicitis, rheumatism, etc.; (4) those whose physical condition was not normal, as high pulse, albumin in urine, etc.; (5) those who were distinctly overweight or underweight. In order to determine the relative mortality a standard was prepared, representing average mortality among insured lives, based upon the experience of the forty-three companies among all their insured.

Occupation.—There were ninety-seven different occupations in which the relative mortality was determined. Only three are given here.

The mortality is high among railroad men. Among locomotive engineers it was 60 per cent. in excess of that experienced among the insured as a whole, which is equivalent to five years' reduction in the average lifetime. If these engineers had been in a non-hazardous occupation there would have been about 337 deaths, and there actually were 541 among them. Such a death rate can be and has been reduced, as is proved by the splendid efforts of some of the railroads to educate their employees to assist in keeping down the accident and death rates.

In the mining industry the mortality (in all underground metal mines) was more than double that among other insured lives. This is equivalent to an average reduction of fully nine years in their lifetime. Pneumonia and tuberculosis cause a very high death rate among miners, and this could be prevented through systematic education.

Among saloon proprietors, whether they attended to the bar or not, there was an extra mortality of 70 per cent.; and the causes of death indicated that a free use of alcoholic beverages had been responsible for many of the deaths. The mortality among those connected with breweries was about one-third above the normal. The wholesale liquor dealers had an extra mortality of about one-fifth. In the fourteen subdivisions of the trades connected with the manufacture or sale of alcohol, there was only one class which had a normal mortality, which was the distillery proprietors.

Defects in Personal or Family History.—There were forty-nine classes under this head. Only one or two are given here.

It has generally been assumed that syphilis increases the death rate but no facts relating to this country have been published heretofore showing the serious effect of that disease on mortality. Only the better types of cases have been accepted by the companies. The same results have been found in other countries. All of the cases insured had received medical treatment before application for insurance; and one class had had one year's freedom from any symptoms, yet the excess mortality was 80 per cent.—a decreased lifetime of about six years.

Among men who had taken alcohol occasionally to excess in the past, but at the time of their insurance had been considered satisfactory, the extra mortality was over 50 per cent., or a reduction in the average life of these men of over four years. Men who used alcoholic beverages daily but not to excess were divided into two groups: (*a*) those who took two glasses of beer, or a glass of whiskey, or their equivalent, a day; (*b*) those who took more than the above, but were not considered by the companies to drink to excess. The mortality in the second group was found to be fully 50 per cent. greater than in the first—due probably to their gradual increase in daily consumption after having applied for insurance. Among the men who were formerly intemperate but who had reformed for at least two years prior to their acceptance by the companies, the extra mortality was fully 30 per cent., or a reduction in their average lifetime by about three years.

The deaths from tuberculosis of the lungs among those who had had pleurisy within five years prior to insurance were three times the average number. Care should be taken to guard against infection from tuberculosis after an attack of pleurisy.

Overweight and Underweight.—It may be said in general that, except at young ages, the longevity of persons above the average weight is not affected by a family history of a parent or a brother or sister dead from tuberculosis. It has been indicated, however, that where there is a predisposition to light weight with a family history of tuberculosis, there is found a condition favorable to the development of this disease. Among young risks insured when at least 25 pounds under the average weight, and having lost a parent or brother or sister from this disease, five out of every ten deaths were due to tuberculosis. Among risks with the same family history but insured at slightly overweight, three out of every ten deaths occurred from this trouble; while among those distinctly heavy one out of every ten deaths was from tuberculosis. Among those who had no family history of tuberculosis, but were very light in weight, the death rate from this disease was high. A sufficiency of nourishment, with sane precaution against contagion, leaves little to fear from tuberculosis.

There is no doubt that marked overweight has a material effect in decreasing length of life, especially at the middle and older ages. Among men forty pounds above the average weight the lifetime of those who entered the companies at age forty-five was about four years less than that of men of normal weight. The public should understand that marked overweight is a serious handicap to length of life. The adage, "Laugh and grow fat," is not good advice for the man or woman who is inclined to be heavy. Diabetes, Bright's disease, heart disease, and apoplexy cause a large proportion of the deaths among the overweights. While the overeater does not exert such a bad social influence as the excessive drinker, the former is also shortening his life by lack of moderation.—Association of Life Insurance Presidents, December 10, 1914.

Book Reviews.

MEDICAL JURISPRUDENCE—A Statement of the Law of Forensic Medicine. By ELMER D. BROTHERS, B.S., LL.D., Member of the Chicago Bar; Lecturer on Jurisprudence in the Medical and Dental Departments of the University of Illinois, and in John Marshall Law School. Price $3.00. St. Louis: C. V. Mosby Co., 1914.

THIS volume contains the substance of the lectures delivered by the author to medical, dental, and law students. It will be valuable, chiefly, to those who are attending the author's lectures. Other readers will find in it a brief description of the many legal matters which either concern the physician or overlap the study of medicine. The author is at his best in the purely legal aspect of his subject; when trenching on medical ground he is apt to slip, as when he speaks of a *fracture of the submaxillary*. The sections on wounds and on poisoning are too brief to serve any useful purpose, and there is nothing at all on deaths from violence, personal identity, signs of death, and presumption of death, and of survivorship. We do not know whether the author or the printer is responsible for "*de minimus non curat lex*—the law does not concern itself with triflers," on page 173.

LOCAL ANESTHESIA; ITS SCIENTIFIC BASIS AND PRACTICAL USE. By Prof. Dr. HEINRICH BRAUN, Obermedizinalrat and Director of the Kgl. Hospital at Zwickau, Germany. Translated and edited by PERCY SHIELDS, M.D., F.A.C.S., Cincinnati, Ohio. From the third revised German edition. Octavo, 399 pages, with 215 illustrations in black and colors. Price, cloth, $4.25 net. Philadelphia and New York: Lea & Febiger, 1914.

LOCAL anesthesia, considered of use in but a very limited field a decade ago, has recently been widely employed and seems to be continually gaining adherents. With many surgeons it is now the method of choice in operating for hernia, goiter, and many other conditions where general anesthesia is customarily used. The credit for such perfection in technique as to allow its use in major operations cannot be ascribed to any one man—it has been a gradual development from the work of Corning, Reclus, Schleich, Cushing, Kocher, Crile, Braun, and a host of others; but Braun's work has been of such preeminent value in establishing local anesthesia on its present basis that we must agree with the statement in the translator's preface that Braun "has justly been called 'the father of local anesthesia.'" This is the first English translation of Braun's work, and the translator and publishers deserve the thanks of that host of English and American surgeons who are interested in local anesthesia, and who lack a reading knowledge of German. In this work the entire subject is covered. Starting with an historical sketch, giving an outline of attempts at local anesthesia from the earliest recorded times to the discovery of cocaine, Braun proceeds with the discussion of sensation and pain, anesthesia and anesthetic methods, the pain-relieving action of nerve compression and anemia, anesthesia by means of cold, general properties, and the methods of using local anesthetic agents; the value, indications, and general technique for local anesthesia, and numerous other topics whose understanding is essential for the intelligent use and further development of local anesthesia. The description of the technique in the anesthetization of all the various tissues and regions of the body in which local anesthesia is available is found in the second half of the book. In all the recent works on local anesthesia Braun is extensively quoted. Here we have the entire subject presented by this indefatigable worker, a most valuable guide for all who appreciate the wide range of applicability and comparative safety of this method.

ACUTE GENERAL MILIARY TUBERCULOSIS. By Prof. Dr. G. CORNET, Berlin. Translated by Dr. F. S. TINKER. Liverpool. Price, $1.50 net. New York: Paul B. Hoeber.

THIS little volume by Cornet, one of the greatest students of tuberculosis, well translated by Dr. Tinker of Liverpool, gives an excellent résumé of our present knowledge of the most serious of tuberculous invasions. Cornet believes in the causal relationship of the vascular tubercle to miliary tuberculosis. He very aptly says "to explain the sudden inundation of the blood with bacilli otherwise than by a massive invasion or a rupture into the vessel itself is scarcely imaginable." The origin of vascular tuberculosis, he explains, is in bacilli from a nodule lying in the periphery of a vessel which by continuous growth gets into the interior of the vessel wall. The pathological consequences of such a rupture and subsequent invasion of the various organs are carefully described and the conditions favoring a miliary invasion are enumerated. According to this author, any irritations, mechanical or otherwise, which affect the tuberculous focus, favor the development of miliary tuberculosis. Trauma, pregnancy, and typhoid fever are mentioned as predisposing causes. In the chapter on pathology the very frequent occurrence of the tubercles in the choroid and in the thyroid glands are mentioned. The rest of the pathological description does not offer anything new. Emphasis is laid upon the frequency with which one finds a mixed infection in miliary tuberculosis (*Bacillus pyocyaneus* and *Bacillus pyogenes*). The well known symptomatology and physical signs necessary to make a positive diagnosis of miliary tuberculosis are clearly described.

Rather pathetic is the fact that out of the 100 pages of the volume, including 10 pages of bibliography, hardly a page and a half is devoted to prophylaxis and therapy. When the author says "the only rational prophylaxis of miliary tuberculosis depends on the prophylaxis of tuberculosis in general," he is right, but since he himself acknowledges that a cure of miliary tuberculosis is not absolutely impossible, it would seem that a little more space might have been devoted to the therapeutic aspect of the disease. The reviewer fails to see mentioned a most valuable remedy in miliary tuberculosis, which is tannic acid, or, better yet, gallic acid. Of judicious aerotherapy, valuable even in miliary tuberculosis, no mention is made. Two cases of cures are reported, one treated with iodide of potassium in large doses, the other with Marmoreck serum. The book deserves a careful study and the translator is to be congratulated on having given this excellent monograph to the English speaking medical profession.

DIETETICS, OR FOOD IN HEALTH AND DISEASE. By WILLIAM TIBBLES, LL.D., M.D. (Hon. Censor), Chicago; L.R.C.P., Edinburgh; M.R.C.S., England; L.S.A., London; Medical Officer of Health, Fellow of the Royal Institute of Public Health, etc.; Author of "Food and Hygiene," "Foods: Their Origin, Manufacture, and Composition," "Diet in Dyspepsia," "The Theory of Ions," etc. Price, $4.00. Philadelphia and New York: Lea & Febiger, 1914.

DR. TIBBLES is well known as an authority upon diet and as the author of several standard works on the subject. There is no doubt but that diet is an important, perhaps the most important, factor in the obtaining and conservation of good health. As the author points out, the value of the diet is generally very much underestimated and remarkable results can and are being achieved every day by this very easy therapeutic method. Also diet is almost as much a part of preventive medicine as of therapeutics and *pari passu* advances with them. Dr. Tibbles' new work comprises all that is new in our knowledge of dietetics, including a consideration of the enzymes, of the lipoids, of the salts, and of the vitamines. The book is well written and arranged, and should hold a prominent place among works of a like nature.

A TEXT-BOOK OF GENERAL BACTERIOLOGY. By EDWIN O. JORDAN, Ph.D., Professor of Bacteriology in the University of Chicago and in Rush Medical College. Fourth Edition. Price, $3.00 net. Philadelphia and London: W. B. Saunders Company, 1914.

THIS fourth edition of Jordan's text-book has been revised sufficiently to bring the matter up to date. A new chapter on Filterable Viruses has been added and the sections on Streptococcus Sore Throat, Whooping Cough and Poliomyelitis have been largely rewritten. The style of the book is admirable so that it makes fascinating reading. The subject matter is naturally condensed in a book of this size but it includes all that it is essential for a student to know and there are numerous references to aid the seeker after further and more complete information. The importance of the disease and the work which has been done on its bacteriology would seem to render Pertussis worthy of a place in the regular text rather than in the appendix. The chapters on diseases of plants and the bacteriology of the soil, air, water, and several industries make interesting reading. The book can be highly recommended.

With Sabre and Scalpel—The Autobiography of a Soldier and Surgeon. By John Allan Wyeth, M.D., LL.D. Illustrated; $3.00 net. New York and London: Harper & Brothers, 1914.

This book is almost unique in one respect, in that it tells of the career of a man who played several parts in the battle of life and finally made a success of the practice of medicine after abandoning it for some years. As the title indicates, the first part of the book deals largely with war, and Dr. Wyeth, who as a loyal Southerner fought in the Confederate Army until he was taken prisoner, gives an extremely interesting and instructive history of the great American war as he saw it from the ranks. But the author states that the chief purpose of the volume was to record from personal observations something of the social, economic, and political conditions, which prevailed in the South before, during, and immediately after the Civil War. This object has been fulfilled to the letter, and his tales of the South in the periods referred to are worthy of close attention, being the result of the observations of an acute student of men and affairs. Moreover, it is written in a breezy, expressive style and provides really fascinating reading.

As for the part treating of his professional life little need be said, as probably every medical practitioner in this country is aware of the author's accomplishments in this direction. The founding of the New York Polyclinic Medical School has been Dr. Wyeth's "summum opus" and will remain to keep his memory green. Whoever wishes to read the record of a stirring, versatile and successful career told in an interesting manner cannot do better than open the pages of "With Sabre and Scalpel."

Anoci-Association. By George W. Crile, M.D., professor of surgery, School of Medicine, Western Reserve University; visiting surgeon to the Lakeside Hospital, Cleveland; and William E. Lower, M.D., associate professor of genito-urinary surgery, School of Medicine, Western Reserve University; associate surgeon to the Lakeside Hospital, Cleveland. Edited by Amy F. Rowland. Original illustrations. Price, $3.00 net. Philadelphia and London: W. B. Saunders Company, 1914.

This small volume of 260 pages contains a good deal more than its title suggests. Part I reports an experimental study of some phases of the kinetic theory of shock; Part II covers the subject of the practical prevention of surgical shock; and the appendix contains chapters on the administration of nitrous-oxide-oxygen anesthesia, the detailed technique of special operations, the relation of anoci-association to the preoperative and postoperative care of patients, and a description of an apparatus for the manufacture of nitrous oxide gas. This last section is purely technical and need not hold our attention further. The experimental studies of the senior author on shock and its prevention have contributed a great deal to our understanding of this important surgical condition and have unquestionably placed in the hands of the operator a means of preventing, to a certain degree at least, severe postoperative reactions. Many surgeons have expressed their opinion that the blocking of centripetal stimuli by anesthetizing the main nerve trunks leading from the operative field has reduced the mortality in primary operations after crushing injuries. Nevertheless, statistics on the subject are still insufficient to warrant too strong a statement as to the value of the method, especially as operative results without nerve blocking have greatly improved under the modern methods of giving anesthesia. There is unquestionably a great advantage in limiting preoperative shock to patients, especially those suffering from diseases in which the nervous system is affected, as in exophthalmic goiter, and here perhaps will be the chief value of what Crile has termed anoci-association. Great stress is laid upon the rate of heart beat before and after operation, as indicating the value of the method, but patients differ so much in this regard that it is not as yet possible to draw conclusions. The question of extensive infiltration with local anesthesia is also not finally settled. Some surgeons claim that the sum total of pain suffered by the patient after the infiltration anesthesia has passed is just as great as without it, and that the pain comes at a period when the effects of the ether anesthesia have worn off, necessitating larger doses of some sedative to avoid bad results. Whether there is a reduction of tissue vitality by such infiltration has also not yet been decided; but it is believed by some that the danger of infection is increased. In prostatectomies, for example, when by the suprapubic method the operation can be done in one or two minutes under primary anesthesia, it would seem that nothing could be gained by extensive infiltration; and it is to be doubted whether the operative results in this class of cases would be improved by local blocking. Whether the attempt to place the phenomena of shock on a morphologic basis by the study of minute changes in the nerve cells will succeed is very doubtful. We know too little of the structure of normal nerve cells, even after years of study, to be able to draw such far-reaching conclusions as are drawn in the first chapter of this work. The illustrations are not convincing. The chapter on the technique of nitrous-oxide-oxygen anesthesia is excellent, but we note with interest the statement that the patient is never touched or restrained until he is quite asleep. In the last operation which the reviewer saw at Dr. Crile's clinic the patient was held on the table by an orderly and two nurses in quite the old-fashioned pre-anoci way, and at no time was consciousness of the pain of operation lost. While the book is written in a rather high and optimistic key, there is no question that not only the experimental work but the clinical results tabulated also are extremely suggestive and contain a considerable portion of matter which will ultimately become a permanent part of surgical technique. No one who is doing surgery can afford to neglect many of the suggestions which it contains.

A Manual of Physiology with Practical Exercises. By G. N. Stewart, M.A., D.Sc., M.D., Edin., D.P.H., Camb., professor of experimental medicine in Western Reserve University, clinical physiologist to Lakeside Hospital, Cleveland; formerly professor of physiology in the University of Chicago; professor of physiology in the Western Reserve University; George Henry Lewes, student; examiner in physiology in the University of Aberdeen; senior demonstrator of physiology in the Owens College, Victoria University, etc. With colored plate and 467 other illustrations. Seventh edition. Price, $4.00 net. New York: William Wood and Company, 1914.

The seventh edition of this well known manual shows a great deal of revision with the introduction of new matter, though the book still remains within the limit of some eleven hundred pages. Its particular value lies in the intimate combination of theoretical material and practical directions for experimental work. The chief novelties are naturally embodied in the chemical portions, as physiological research has lately been concentrated along that line. Even Abel's recently devised apparatus for obtaining diffusible substances from the blood is described. The chapter on vision and methods of eye testing is the most practical in any physiological textbook known to the reviewer. It is unfortunate that the Franklin color vision theory has been omitted; certainly it is as useful in explaining color blindness as either the Young-Helmholtz or Hering theory. It is also to be regretted that the author does not give references to original papers of which he occasionally quotes the authors' names. It is not always possible to find the originals of such articles except by prolonged searching and more familiarity with bibliographical methods than the average student possesses. The only criticism from the mechanical side is that the paper is rather thin so that the print and cuts often show through, making the reading of the text somewhat difficult.

Cunningham's Manual of Practical Anatomy. Revised and edited by Arthur Robinson, Professor of Anatomy in the University of Edinburgh. Sixth edition. Volume First: Superior Extremity; Inferior Extremity; Abdomen. Volume Second: Thorax; Head and Neck; with 249 illustrations in the text and 22 plates, six of which are in colors. Price, $5.50 net per set. New York: William Wood and Company, 1914.

Six editions of this work have been published within a period of eighteen years, and during this time it has maintained an enviable record as a student's guide for the dissecting room. The present edition shows evidence of careful revision of the text, with new illustrations added and older ones omitted. One of the noteworthy features in the series of radiographs of parts of the normal body, which enable the student to compare the results of his dissections with the radiographic appearances of these parts. The terminology used is that of the Basle Anatomical Nomenclature, but the older terms are used side by side with the newer ones.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 21, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Neurology and Psychiatry.

The Cerebrospinal Fluid in Health and Disease.—DR. CHARLES H. FRAZIER of Philadelphia, Pa., presented this communication. He said that the time would be spent in taking stock, as it were, of our present knowledge of the cerebrospinal fluid in the light of modern interpretation. The original conception of the cerebrospinal fluid as a transudate had long since been discarded. A study of the choroid plexus left little room for doubting that the cerebrospinal fluid was a secretory output. This view was based upon a study of the structure of the plexus in different classes of vertebrates and upon the histological changes in the gland following the administration of substances with a hypersecretory effect. As still further proof of the secretory theory stood the intra vitam staining experiments of Goldmann and his demonstration of the permeability of the choroid plexus. When foreign toxic substances were injected into the circulation the choroid plexus acted as an impermeable filter and prevented their entrance into the cerebrospinal fluid; on the other hand, when the dye was injected into the subarachnoid space the brain and cord were at once stained. This phenomenon threw a side light on salvarsan therapy. It was well known that after salvarsan was injected intravenously, only an infinitesimal amount, if any, could be recovered from the spinal fluid. Might this not be due to the character of the choroid plexus? Thus it would seem more rational to inject salvarsan directly into the ventricles or subarachnoid space in cerebrospinal lues. The production of artificial hydrocephalus was also a suggestive bit of testimony in favor of the choroid plexus as the source of the cerebrospinal fluid, as was also the fact that a decided increase in the rate of flow had been observed after the injection of the extract of choroid; and, furthermore, if the pressure of the cerebrospinal fluid was the same as that of the capillaries there could be no escape of fluid from the capillaries in the form of a filtrate or transudate. In considering the question whether the cerebrospinal fluid had more than one source, Dr. Frazier stated that there were a number of observers, with whom he was disposed to agree, who conceded that the greater part of the fluid was derived from the choroid plexus, but who held that some was derived from the perivascular system of the nervous tissues. The probability of a dual supply brought up the question whether the cerebrospinal fluid could be in part a true secretory product, and in part an effusion or an infiltrate. They had approached this problem from the laboratory viewpoint and were attempting to eliminate the choroid plexus altogether, so that a differentiation between these fluids of dual origin might be possible. As to the functions of the cerebrospinal fluid aside from those of a purely physical nature such as the maintenance of uniform pressure, it performed functions analogous to those of the lymph node. It might be said that it brought oxygen and glycogen to the tissues and carried away carbon dioxide and the products of brain metabolism, normal and pathological. Dr. Frazier stated that he attached a great deal of importance to high cerebrospinal pressure, both in matters of diagnosis and in the plan of treatment. There was considerable difficulty, however, in any attempt to formulate standards or gauges, or to make comparative studies of the pressure, and hence it was desirable that clinicians in this country should adopt a standard instrument and that certain regulations be formulated under which observations should be made. He had found a small mercury manometer the most convenient for all practical purposes. It seemed commonplace to call attention to the fact that in every disease in which there was a departure from the normal in the quantity of cerebrospinal fluid, it was in the direction of increase and not decrease. They had also found that coincident with the increased flow there was a fall of blood pressure and that just as soon as the blood pressure returned to normal the flow would begin to slow down. The question to be solved here was "What were the factors which so disturbed the balance between secretion and absorption as to be accompanied by a superabundance of fluid, and could the one or the other be controlled?" In their endeavor to solve this problem many experiments were made as to the effect of different substances, but the result of all was hyperactivity. At length they discovered in thyroid extract a substance which of itself had a specific inhibitory effect upon the action of the choroid plexus. Alcoholic extracts of thyroid gland were practically inert. Diiodotyrosin, a synthetic product identical with that found in the thyroid, had the same retarding influence upon the output of cerebrospinal fluid, although not in the same degree as the thyroid tissue itself. With the substances which acted as cerebral lymphagogues must be included those which caused a deficient oxygenation with the resulting accumulation of carbon dioxide in the blood. In this group were pilocarpine, amyl nitrite, anesthetics, and narcotics. The rate of the flow of the cerebrospinal fluid was practically uninfluenced by the ligation of the common carotid arteries. The companion problem to secretion was that of absorption, and upon this much light had been shed by recent investigations. The general statement might be accepted that the major part of the cerebrospinal fluid left the subarachnoid space *via* the venous channels rather than *via* the lymphatics. Fluid did escape by the nerve sheaths and into the lymphatic system, but only very slowly and in comparatively small quantities. The system of absorption was an extremely elastic one. The author stated that if he might express an opinion based largely on clinical, but partly on laboratory observation, he would say very definitely that the amount and rapidity of absorption was in proportion to the total area of subarachnoid space available. Before the problem of absorption could be solved they must know more of the pathological factors which retarded the process and which of the various factors might prevail in a given condition. What was the pathological factor in hydrocephalus, in epilepsy, in brain tumor? The author finally considered the clinical conditions in which the cerebrospinal fluid was an important factor. In all forms of meningitis, apart from lumbar puncture to relieve tension, there were no measures to be considered other than the use of specific sera when available. He stated that he had yet to see a case of tuberculous meningitis of acute type recover when pressure was relieved by decompression; nor had he heard of any case of suppurative meningitis which had been cured by drainage of the cisterna magna. Serous or aseptic meningitis presented very positive indications for relief of pressure by such operative measures as subtemporal or suboccipital decompression. Increased intracranial tension in brain tumors was the result of a secondary hydrocephalus, whether the tumor was cortical, subcortical or basal, large or small, malignant or benign. Tumors, irrespective of their size or seat, might exist without signs of tension. Palliative treatment in brain tumors resolved itself largely into the problem of dealing with the associated hydrocephalus, and, therefore, accompanying decompression or preceding it, puncture of the corpus callosum should always be thought of. In discussing the subject of hydrocephalus the author said that in the production of artificial hydrocephalus in their experimental work they had found it possible to differentiate types of hydrocephalus, that was, whether it was of an obstructive or a non-obstructive type. In the obstructive type the chief pathogenic factor was delayed absorption, and the treatment, therefore, became a problem of drainage. Of the non-obstructive type he could not speak so dogmatically, although by deduction one would ascribe it to a state of hypersecretion, and if this were true treatment should be aimed at the secreting organ, the choroid gland. In one of several cases of hydrocephalus now under treatment with thyroid extract the child at last report seemed apparently normal. This was mentioned that others might be encouraged to apply this treatment in suitable cases in order to determine its efficiency.

Professor PIKE of Columbia University said that his attention had been called to the subject under discussion because of a series of experiments he had made in collaboration with Dr. J. Gordon Wilson upon the labyrinth to determine if possible some mechanism in the patients who were afflicted with vertigo. There were some things brought out which led him to believe that the pressure of the cerebrospinal fluid was one of the agencies in the causation of vertigo. He thought that perhaps it would be better in discussing the subject of the cerebrospinal fluid if he would say a few things which might serve as a biological, or rather physiological, background for what Dr. Frazier had told them. The question has arisen whether the cerebrospinal fluid

was a product of secretion of certain gland cells or merely the product of dialysis from the blood vessels. In general it might be considered that the formation of the body fluids by mere filtration through the blood vessels, subject to variation in quantity with every variation of pressure in the blood vessels, would not be a good arrangement. Tigerstedt has pointed out that, although the endothelial cells of the blood vessels might be extremely thin, that in itself was not to be considered as evidence that they might not restrain very efficiently those things which should not pass through. Stefani stated some years ago that carbon dioxide would produce at first a dilatation of the blood vessels in the region in which it was allowed to accumulate. There was now a considerable body of fact tending to show that the variations in the caliber of blood vessels going to particular organs were sometimes brought about by the products of metabolism of these organs without any necessary direct effect upon the central vasomotor mechanism. It is possible that the varying needs of the tissues in general are met by the changes in blood and lymph supply occurring in response to the local action of these products of metabolism. The peculiar conditions of the cerebral circulation are of interest in connection with the formation of cerebrospinal fluid. There was (1) a rigid brain case, (2) an incompressible brain substance occupying most of the space, and (3) incompressible fluids filling up all the remaining space. No more material, fluid or otherwise, could be introduced without crowding out something else that was already present. Increase in arterial flow could be accomplished only at the expense of decrease in volume (1) of venous blood or (2) of cerebrospinal fluid if the cerebral arteries dilated. The flow of blood through the brain might possibly be increased without change in volume of the vessels, if the systemic blood pressure rose, either appreciably or considerably. There was no good evidence, if one accepted Cushing's view, of a vasomotor system in the cerebral vessels which acted in harmony with the systemic vasomotor nerves. The nerve cells of the central system might be considered to be protected from sudden changes in blood supply through these peculiar general conditions of the cerebral circulation. Nor did the possibility of sudden variations in blood supply to a particular part of the brain through the agency of cerebral vasomotor nerves seem a likely one. One must consider what other possibility of variation in nutrition with changes in activity existed for a central nerve cell. Such a possibility existed in the cerebrospinal fluid if it was regarded as a nutritive fluid. Not only did the choroid plexus secrete the greater part of the cerebrospinal fluid, but extracts of the choroid plexus when injected subcutaneously increased the flow of the fluid. Brain extracts also gave an increased flow of cerebrospinal fluid, and normal cerebrospinal fluid gave an increased flow when injected. Pathological fluid may act differently. Cerebrospinal fluid from patients suffering from general paralysis, with positive Wassermann reactions, gave increased flow (Dixon and Halliburton). If they imagined that the brain cells produced during metabolism certain substances which in their turn acted upon the cells of the choroid plexus to produce a greater flow of cerebrospinal fluid, they have a mechanism by which the varying needs of the brain cells might be met. The seat of formation of this fluid and its course through the subarachnoid spaces to the cerebral cortex as well as to the surface of the spinal cord fits in with the view that the cerebrospinal fluid was a nutritive fluid. Thus absorption after spreading out on the surface of the cerebrum became a necessity if the nutrition of the cells of the central nervous system was adequately to be provided for. Such a view seemed plausible in the light of their present knowledge, but one could not say that it was demonstrated. The difficulties in the way of studying the manner of formation of the cerebrospinal fluid were very great—much greater in many ways than those encountered in the study of the salivary glands, and they were not able as yet to answer all of the questions concerning the secretion of saliva. Dr. Pike said he should not close without expressing the appreciation of a laboratory man of the work of a surgeon who had applied the experimental methods of the physiological laboratory to the solution of problems in clinical surgery as Dr. Frazier had done.

Dr. David M. Kaplan said that he believed from the title of Dr. Frazier's excellent paper that he was expected to speak of the cerebrospinal fluid, not only in reference to hydrocephalus, but also of the findings in other pathological states. It was not so long ago that the entire subject of cerebrospinal fluid in health and disease could have been covered very conveniently in one session but to-day so much information had been gathered that a full consideration of the subject would require many such meetings. Aside from the infections in which one found the responsible microorganisms, the cerebrospinal fluid also showed changes due to such general disturbances as diabetes, eclampsia, nephritis, and jaundice. In diabetes the presence of acetone was frequently a forerunner of a diabetic coma. In eclampsia, besides the increase in chlorides, appreciable quantities of lactic acid had been demonstrated. In nephritis only those forms of the disease gave rise to uremic states that showed the accumulation of urea in the cerebrospinal fluid. Where the renal impermeability was a mineral one, causing a retention of chlorides, and clinically shown by anasarca, uremia, as a rule, did not develop. The physiological limits of urea in the cerebrospinal fluid as stated by Mestrezat was 1 per cent. A fluid showing 3 per cent. or more was of very grave significance. In icteric states one found one or the other constituents of bile. In the experience of the speaker such fluids would occasionally show a positive Wassermann reaction, although no evidence of lues could be obtained during life or at the post mortem. In fact, a definite quantity of ox-gall added to a normal serum would give rise to a positive Wassermann reaction. Although this was not a discussion of the Wassermann reaction, it must be stated that the real biological meaning of the positive Wassermann reaction still remained the "will-o'-the-wisp" of the serologist. The very interesting contribution on the spinal fluid in anterior poliomyelitis by Drs. Peabody, Draper, Dochez, and others showed that the acute stage in this disease was invariably accompanied by a polynucleosis in the cerebrospinal fluid, which reached its height in the preparalytic stage. The more chronic forms of the disease showing the paralyses were more often accompanied by an excess of protein matter and a variable pleocytosis. In the clinical picture known as "combined sclerosis," where the sensory and motor tracts were simultaneously involved, one frequently, though not always, found a marked excess of protein which was as a rule unaccompanied by a pleocytosis. In cord compression in general one usually found in the spinal fluid a mass of coagulation of protein matter which showed no pleocytosis and was frequently discolored yellow, known as xanthochromia. These yellow fluids sometimes gave the iron reaction and at others did not, and hence they must be considered as having more than one origin. The discolorations and the peculiarly absent copper reducing substance was more often met with in endotheliomata than in glioses of the cord. A clinical entity described by Drs. Elsberg and Kennedy in which the disease affected the spinal cord or the medullary conus also showed this paradoxical reaction of a cell-free fluid rich in protein matter. In the various diseases of the nervous system caused by syphilis, neurologists who made extensive use of the information gathered from the study of the cerebrospinal fluid tended to consider syphilis and general paresis as the two extremes from the diagnostic, therapeutic, and prognostic point of view, and assigned to tabes an intermediary position. There were certain unmistakable features that characterized the great majority of fluids of the two extremes, namely, cerebrospinal syphilis and general paresis, which peculiarities were only occasionally to be found in tabes. They found in cerebrospinal syphilis the highest and in general paresis the lowest cell counts, of course barring fluids that must be thought of as exceptional. A fluid from a case of general paresis would always reduce copper, so much so that when this reduction was absent one was justified in excluding the diagnosis of general paresis. In offering diagnostic suggestions from an analysis of the cerebrospinal fluid one never depended upon that feature alone, but correlated all the abnormal phenomena. In general paresis the characteristic precipitation of colloidal gold was a very striking and very constant feature. This reaction, together with a positive Wassermann reaction, a low cell count, and protein excess, meant only one thing, despite the fact that these findings would occasionally be obtained in patients who presented very few symptoms suggestive of general paresis. From the few remarks offered regarding lues of the nervous system, it was evident that in selecting fluids the serologist was permitted to give a diagnostic opinion; in the greater majority of instances, however, such advice should only be offered together with the clinical facts in the case. From the proper study of

the cerebrospinal fluid one obtained not only diagnostic hints, but also valuable therapeutic and prognostic suggestions.

Dr. T. Stuart Hart remarked that it had been said all so-called surgeons could be divided into two classes—carpenters and real surgeons; it was needless to point out the class to which the speaker of the evening belonged. Dr. Frazier's careful and brilliant work had added much to our slender stock of knowledge in this important field. His success had been in a large part due to the fact that for the moment he had allowed the relief of the pathological condition to occupy a secondary place. He had used the pathological condition to solve the problems of physiology. Some day it might be possible for a carpenter to cure a case of hydrocephalus; but if this ever came true it would be because a real surgeon has preceded him with work such as has been presented to us this evening. The real surgeon, in addition to his special knowledge, possessed many of the best qualities of the pathologist, the neurologist, and the internist. Dr. Frazier had told them much of the *quantitative* changes in the spinal fluid induced by changes in blood pressure, the injection of drugs, extracts of organs, etc., and he wished to ask whether he had had an opportunity to study the *qualitative* changes under these conditions, and if so, if he would point out a few of the more important.

Dr. B. Sachs said that the cerebrospinal fluid was a peculiar one and seemed to differ from other serous fluids of the body. He could not help feeling, however, that it quite closely resembled other serous fluids in the body. Dr. Frazier's experiments had shown that the cerebrospinal fluid could be introduced into the thoracic cavity without damage being done, and it had been shown that there was a close resemblance between the two fluids. Dr. Sachs could see no objection to considering this fluid as having a nutritional value and at the same time having a mechanical function to perform. These qualities could be attributed to other fluids of the body and the cerebrospinal fluid was not an exception to the rule. With regard to the manner of secretion, that the choroid plexus played a very important rôle and had an important relation thereto, there was little doubt. If one reflected and considered how the cerebrospinal fluid differed from other fluids he would learn that there was a remarkable rapidity of secretion under certain conditions. They all had had that experience in the service in all their hospitals. In cases of central nervous diseases, particularly tabes and central lues, the patients had been made comfortable after lumbar puncture. When the fluid pressure was measured and found to be high it was remarkable how it would come down after lumbar puncture had been performed; but in a few hours there would appear evidences of almost the same quantity. These facts regarding the cerebrospinal fluid were of great importance and of great physiological interest. Another point Dr. Sachs had observed, which was of interest regarding the cerebrospinal fluid not only for therapeutic reasons but from a diagnostic standpoint as well, was the signal failure in the detection of cellular contents of the cerebrospinal fluid in cases of neoplasm in and around the spinal cord.

Dr. David John Kaliski said that there had been few facts added in the discussion, either substantiative or contradictory, to their knowledge of the cerebrospinal fluid as outlined by Dr. Frazier in his authoritative paper. Regarding the excretion of drugs by the choroid plexus some examinations by Sachs, Straus and Kaliski of the spinal fluids had been made by Professor Benedict in the laboratory of Cornell University, and they had been surprised to find that arsenic introduced intravenously had been excreted within twenty-four hours by the choroid plexus and had been detected in the cerebrospinal fluid. This was rather contradictory to others' findings and to the usual views. These facts were of great importance in the treatment of syphilitic diseases of the nervous system and should lead one to pause and not make dogmatic statements regarding the absence of secretion from the choroid plexus after intravenous medication. It was rather far fetched, in view of the rapid absorption of the spinal fluid, to look upon intraspinous medication (salvarsanized serum) as a means of curing parenchymatous diseases of the central nervous system such, for example, as paresis. He could not substantiate the statement of Kaplan of the presence of bile in the cerebrospinal fluid or of its effect upon the Wassermann reaction. He had never been able to find that the presence of bile in the serum ever caused the reaction to become positive in a normal case.

Dr. Edward D. Fisher said that the investigations of Dr. Frazier were of great interest whether considered in the light of hydrocephalus or in their bearing on the treatment of diseases of the nervous system, especially syphilis. Our knowledge of the cerebral spinal fluid, whether as to its being a secretion of the choroid plexus, which the speaker regarded as a secreting gland or in part at least due to the vascular system, had always been uncertain. Whether again it was nutritional in function or only a protective buffer against shock had not been proven. It certainly in disease showed that it was a receptacle for some of the products of disease. The laboratory work done, Dr. Fisher said, he could not discuss, but it would seem to show the reason for the successful treatment of cerebrospinal syphilis by intravenous injection, as probably very little salvarsan entered into the cerebrospinal fluid, but was stopped at the choroid plexus. It was in such disease conditions, which Head called syphilis meningo-vascularis, that we had our best results, while in syphilis centralis (Head) where there was disease of the cells of the central nervous system (parenchymatous disease), the results were very doubtful, tabes and general paresis not responding, except in so far as the vascular lesion was affected. As has been said by Head, it was doubtful whether when intraspinal injections were used the arsenic reached the pericellular spaces, and whether if it reached the cell it did so in large enough amounts to affect the spirochetes. Another question arose as to whether if that were possible it would not be destructive to the cell itself. The question, therefore, of a possible cure in central syphilis or parasyphilis, to use the old name, was still in doubt. This did not do away with the fact that improvement took place, many symptoms being relieved, but it gave an explanation why one got this improvement in the vascular and meningeal manifestations and in those only.

Dr. Louis C. Ager said he was much interested in Dr. Frazier's findings in regard to the action of thyroid in checking the secretion of cerebrospinal fluid, and would like to report briefly a case of hydrocephalus treated in that way. A male infant, eight months old, had an attack of cerebrospinal meningitis in September. He entirely recovered from the acute attack under treatment with Flexner serum. Two weeks later he began to show symptoms of cerebral irritation, and a bulging fontanelle. Thyroid was given by mouth, beginning with a quarter of a grain twice a day and increased in a few days to two and a half grains a day. There was a very pronounced improvement almost at once, but it was merely temporary. Convulsions and vomiting ceased, the appetite improved, and there was a return to normal mentality. In a few weeks, however, the pressure again returned and the circumference of the head increased five centimeters in eight weeks. Practically no fluid could be obtained on spinal puncture, and an attempt was made to tap the ventricles, but the child died on the table.

Dr. Isador Abrahamson believed that while all three factors were concerned in the production of internal hydrocephalus, faulty absorption, in his experience, was the most common and the most important factor. Most often, in increased intracranial pressure, there was a free communication between the cranial and spinal cavities, the intraspinal pressure being directly proportionate to the intracranial. Here, naturally, obstruction as a factor was out of question. Secretory faults could also be excluded in most of these cases, partly because frequent lumbar punctures, while of temporary benefit as in pleuritic effusions, failed to cure these states. In such cases like one now under his care, of luetic serous meningitis, it was a question of failure of the required absorption due to disease of the meninges. Dr. Abrahamson said he would like to put two questions: First—Had Dr. Frazier injected a sufficient amount of choroid plexus substance into animals to evoke an acute internal hydrocephalus, *i.e.* choked discs, vomiting, etc.? Second—Had Dr. Frazier studied the phenomenon of cerebral edema? Both of these problems were in intimate relationship to the question of the causation of internal hydrocephalus.

Dr. Foster Kennedy said that the question of the cerebrospinal fluid having a nutritive value, as was brought up by Dr. Frazier and others, was of interest, and while agreeing with Professor Pike's remarks yet it would appear that potentially it had a high nutritive value. Dr. Kennedy said he had had an opportunity of seeing cases where the cerebrospinal fluid was being lost in streams, in some instances for as long as three or four months. Except in cases of prolonged diarrhea and vomiting in infants, and complete inanition in

adults, he had never seen such extraordinary marasmatic conditions as had thus resulted. Dr. Israel Strauss also had had similar experience in cases of leakage from the cerebrospinal pond. There was one question that Dr. Kennedy thought very important: Dr. Frazier had found that the administration of thyroid gland was capable of producing a reduction in the quantity of the cerebrospinal fluid to one-third the normal flow. A non-alcoholic extract of the gland had been capable in animals and the human patient of curing hydrocephalus due to an increased fluid production. It would be important to know the amount of the gland dosage and the method of administration. If these results could be confirmed in an adequate series of cases there would be opened up therapeutic possibilities in a field heretofore depressingly sterile.

Dr. Frazier, in closing, said he felt well repaid by the lengthy and diversified discussion which the paper had provoked. He was indebted especially to those who in their discussion had suggested so many interesting problems for future investigation and for the new advance of thought which these had opened up. Of particular interest to him was the problem of producing experimentally an artificial hydrocephalus by the injection of choroid plexus, an investigation which he had in prospect. He could not speak in figures as to the relative frequency of the various types of hydrocephalus, according to his classification, *i.e.* the obstructive, the nonobstructive, and the hypersecretory, although he had gained the impression that the purely obstructive was in the minority. Dr. Frazier expressed the hope that their knowledge of the inhibitory effect of thyroid extract upon the choroid plexus would be applied to the treatment of selected cases of hydrocephalus, and the results carefully noted. He was of the opinion that a continuation of the intensive study of the cerebrospinal fluid from the viewpoint of its normal and morbid physiology would lead to a solution of some of the clinical problems in which the cerebrospinal fluid was the dominant factor.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held November 16, 1914.

The President, Dr. Thomas S. Southworth, in the Chair.

Modernized Proctology.—Dr. Samuel G. Gant, in this paper, first gave a résumé of the history of proctology from ancient times, and then referred to some of the important points concerning modern methods of examining for and diagnosticating anorectal diseases, preparing the patient for operation, and carrying out the postoperative treatment. As to the examination, he said there was no excuse for not diagnosticating anorectal affections to-day, because they could be directly inspected by means of the proctoscope and sigmoidoscope, the character of the feces could be accurately determined by macroscopic and microscopic examination, and the extent of such affections, as well as their connection with neighboring organs, could be defined by digital exploration and bimanual palpation. Improved diagnostic technique, largely brought about by proctologists, had also been of great service in clearing up the etiology and pathology of colonic diseases. *Preparation of Patient*—The common practice of older and many modern surgeons of purging patients and deluging their colons the night before and just previous to operation courted annoyance and infection. For hemorrhoidal, polypoidal, fissure, fistula, and other minor operations but a few moments were required to prepare the patient, which was done by the injection of a glassful of soapsuds followed by the mopping of the mucosa with hydrogen peroxide or other antiseptic. Where the bowel was to be amputated or resected for rectal procidentia, stricture, tuberculosis, or malignant disease the patient was kept in the hospital for three or four days and the gastrointestinal tract was at first thoroughly cleansed by catharsis and colonic irrigations with 1 per cent. ichthyol, and then tied up with an opiate or a strong astringent which insured a dry operation field. The parts were never shaved except where sutures were to be used. *Anesthesia*—Local anesthesia was dependable and indicated in about 75 per cent. of all operations, but was contraindicated in complicated cases and in cases where the surgeon was unable to determine beforehand what was required to be done. Personally he had successfully operated upon several thousand rectal patients under eucaine and sterile water local anesthesia, and could say, in comparing the two, that the preliminary injection pain was less with the former, while postoperative pain and bleeding followed eucaine very much more frequently than water anesthesia. Quinine and urea solutions prevented temporary postoperative pain, but this advantage was counterbalanced by the sloughing which occasionally, and the retarded healing of the wound which frequently, followed their employment. He did not employ adrenalin with any local anesthetic, for while it at first caused contraction this was followed by relaxation of the tissues. *Postoperative Treatment*—Both purging the patient and tying up the bowel for several days with opiates were to be condemned. It was his custom to keep his patients on a practically normal diet and not to order a laxative unless the stools showed a tendency toward hardness, when he prescribed mineral oil or small doses of a fruit or other laxative to soften but not liquefy the feces. *Simplification of Treatment*—Proctologists had recently simplified the treatment of lesions and wounds in the lower rectum, and thereby greatly diminished the patient's suffering. The practice of universally cauterizing wounds no longer obtained nor were they packed; pernicious measures often responsible for unhealed sores and fecal incontinence. Instead they were drained, and in cleansing the wound the swab and cotton moistened with water or an antiseptic solution had been substituted for annoying copious irrigations. When healing was tardy it could be satisfactorily stimulated by leaving in the wound a gauze pledget moistened with a solution of silver nitrate (6 per cent.), ichthyol (10 per cent.), or balsam of Peru (20 per cent.); but where the tissues were irritable and rebelled against stimulation methylene blue (10 per cent.) was usually effective. Pain from topical applications could be slightly diminished by the local use of 10 per cent. eucaine or cocaine, but in very sensitive individuals all suffering could be prevented by injecting a solution of eucaine (one-eighth of 1 per cent.) beneath the lesion to be treated. The speaker had long maintained that about 75 per cent. of all anorectal diseases could be cured in the office or by operation performed under local anesthesia and without a lengthy postoperative treatment at home or in the hospital. *Changes in the Treatment of Individual Affections Effected by Modern Proctology: Stricture*—Formerly stenoses, wherever located, had been treated by divulsion, but this very dangerous practice had now been abandoned except when the constriction was within three inches from the anus. The rational treatment of strictures to-day consisted in their division under local anesthesia when low down and, when they were higher up, excising the affected gut or performing colostomy in inoperable cases. *Fistulæ*—Formerly it was held that the curing of a fistula was followed by skin eruptions or lung complications, owing to the arrest of the discharge; but this was now known to be without foundation in fact. By some, even to-day, nearly all fistulæ were thought to be tuberculous, and were therefore not operated upon; yet proctologists knew that tuberculous fistulæ were rare, and when there were such recognized that the patient's vitality should determine whether it was advisable to operate. When the general condition was good, an operation was indicated, because the fistula could then be cured, and the sufferer, thus having one less destructive process to contend with, would stand a better chance of recovering. Many unnecessary deaths had followed operations upon fistula patients with irritative or tuberculous lung lesions owing to their being soaked with ether and retained in the hospital for a prolonged after-treatment. All such deaths could be avoided by doing the operation in the office, under local or gas anesthesia, and permitting the patient, during convalescence, to spend his time in the fresh air. Failure to cure fistula often had been, and still was, due to the fact that the surgeon did not incise all sinuses or was afraid to divide the sphincter. Where the latter was done the patient had frequently suffered from fecal incontinence because of an improper operation or faulty post-operative treatment. Modern proctologists prevented such incontinence by dividing the anal muscle at a right angle, by draining, instead of packing, the wound, and by trimming off the mucous membrance or skin edges which might serve to prevent union of the sphincter borders. *Fissure*—Fissures associated with sphincteralgia did not heal because of the irritable condition of the anal muscle. Recent rents were sometimes healed by keeping the feces of a semi-solid consistence, cleansing the part with moistened cotton, and mild applications of silver nitrate, ichthyol,

or balsam of Peru. When fissures were fully developed and prolonged painful contractions followed defecation, operative measures, and not the old procedure of cauterization, were indicated. For years Dr. Gant had promptly cured all cases of fissure by splitting the anal canal under eucaine, a method which put the muscle at rest, widened the rectal outlet, relieved constipation and straining at stool, and forestalled further trouble. He had abandoned divulsion in aggravated cases because the muscle regained its tonicity before the rent had healed, and the procedure did not insure against recurrence; neither did he excise fissure, since this might be followed by infection and had no advantage over division of the sphincter and anal canal. *Ulcers*—Chronic ulcers near the anus, irrespective of their cause, like fissures, did not heal unless the sphincter muscle were put to rest by divulsion or, preferably, division, and they were treated by curetting and the application of moderately strong solutions of the drugs previously mentioned by means of gauze daily placed in contact with them. Ulcers of the upper rectum were usually associated with some form of colitis, and were to be treated, in connection with the lesions in the colon, by daily medicated colonic irrigations of sufficient strength, introduced by way of the anus or through an appendicostomy or cecostomy opening. The modern treatment of intestinal ulcers was superior to the older method because it aimed at healing the lesion through direct application of the remedy instead of internal medication. *Pruritus Ani*—Ball's operation for the relief of this by severing the nerves of the part from their connection with the skin, which was an elaborate procedure and left extensive wounds requiring weeks to heal when infection occurred, had recently been modified by Lynch and himself, so that it could now be quickly performed under local anesthesia and necessitated no lengthy convalescence. *Hemorrhoids*—Hemorrhoidal operations had been considered serious in former times, and were by no means simple, at least from the patient's viewpoint, as performed by the average surgeon to-day. Under local anesthesia, however, uncomplicated thrombotic hemorrhoids could be laid open, cutaneous ones excised, and internal ones radically operated upon by the clamp and cautery, ligature, or modified excision procedures. Marked improvement had also been made in the technique of operations indicated for the more serious diseases of the lower bowel, such as complex fistula, peri- and pelvi-rectal abscess, malformations of anorectal region, sacrococcygeal affections involving the bowel, stricture, and benign and malignant neoplasms.

Dr. JEROME M. LYNCH said that if every patient passing blood and mucus, or suffering from diarrhea alternating with constipation, were thoroughly examined, we would be able to make an early diagnosis of cancer in a majority of instances. Other symptoms of importance in this condition were the desire to defecate frequently, with a feeling of unfinished stool. These movements were usually explosive in character, and the amount of fecal matter passed small and mixed with mucus or with mucus and blood. In his experience about 25 per cent. of patients suffering from cancer of the bowel had been previously operated on for hemorrhoids. In some cases the diagnosis was made after the patient was under anesthesia, but in the majority much later, and in a great many only when the case had passed the operative stage. When the carcinoma was situated close to the anus the first symptom noted by the patient was the passage of a little blood. Indeed this might be the only symptom present at any time, and such cases had come under his observation. There were other pathological conditions, such as stricture and amebic dysentery, which might give rise to similar symptoms, but by examination of the feces, or even proctoscopic examination, these could easily be differentiated from cancer. The diagnosis of fissure was usually simple, though there were cases in which the patient was more troubled by the secondary complication, sciatica, than by the primary lesion. Such cases were generally treated for the sciatica, when a rectal examination would have revealed the cause of the trouble and a simple operation would have relieved it. Cryptitis was a condition which was frequently overlooked, the patient being usually treated for neuralgia, and after stretching and local applications had failed to relieve he was commonly classified as a neurasthenic. With a bent probe the ulcerated pocket could easily be reached and the correct diagnosis thus be made. The speaker said that he had recently seen a patient who had suffered for four years without getting relief, yet when the little pocket which was the source of his trouble had been opened he received almost instantaneous benefit.

Dr. FRANK C. YEOMANS said that in cases of fistula the essential principles of treatment were to find the pathological opening into the rectum and to lay open the tract. There was no danger in cutting the overlying parts except where the fistula was tuberculous. In this event it was essential to use the actual cautery in order to prevent dissemination of the infection, especially to the lungs. Fistulæ were usually complicated, and on this account it was advisable not to depend upon local anesthesia, except for the simple subcutaneous and submucous types, but to employ a general anesthetic. In the case of tuberculous patients gas and oxygen anesthesia could be used without danger. Clinically speaking, strictures were of two kinds chiefly. Those of the first variety were traumatic or congenital, and were rather rare; the second kind, inflammatory strictures, were comparatively common and were almost invariably of syphilitic origin. Syphilitic strictures were very difficult to treat, and the best method was the employment of gradual dilatation by means of soft rubber (Wales) bougies. If operation became necessary on account of obstruction, temporary colostomy, with subsequent dilatation and local treatment, was advisable. Antisyphilitic treatment, guided by the Wassermann reaction, was, of course, essential, as this would help to place the patient in better general condition, but of itself would not markedly improve the stricture. Amebic dysentery was a condition which should be borne in mind, for personally during the past two years he had treated eleven sufferers from this infection, a number of whom had never been away from New York City. This disease could therefore no longer be considered a purely tropical one. Emetin hydrochloride was the specific for it, and by the hypodermic administration of this drug amebiasis could be controlled or cured in ten days. The course of treatment with it should, however, be repeated for from three to five times, at intervals of a month, to prevent recurrence. In coccygodynia the seat of pain had been originally located in the coccyx itself by Sir James Y. Simpson, who recommended subcutaneous division of all the muscles and ligaments connected with the sides and tip of the coccyx in order to prevent traction. Later, excision of the coccyx had been resorted to, but with unsatisfactory results, except when the bone itself was diseased or deformed by injury. Dr. Yeomans' present opinion was that the affection is a neuralgia or neuritis of the coccygeal plexus of nerves. If this were the case he had conceived the idea that it ought to be possible to relieve the symptoms by injections in and about the nerves of 80 per cent. alcohol, in the same manner as had proved so successful in trigeminal neuralgia. He had now employed the alcohol injections with success in seven cases of coccygodynia.

Dr. GANT, in closing, said that the thing which ought to be emphasized was the diagnosis. Only to-day he had operated on a case of carcinoma in which the patient had been operated on for piles twice during the past year. The trouble was that practitioners did not make an examination of the upper rectum, even when their patients were under ether. The usual history of these cancer patients was slight constipation, pronounced constipation, and constipation alternating with diarrhea, and then severe diarrhea, together with pus and blood in the stools. When, with such symptoms there was progressive loss in weight, one could scarcely make a mistake. He had been glad to hear amebic dysentery referred to. In his opinion the term dysentery should now be dropped altogether, and, looking at the matter from the etiological standpoint, we should speak of amebic colitis, bacillary colitis, etc. Coccygodynia might sometimes be due to neuralgia, but not infrequently we had to deal with a fractured or bent coccyx. In such cases the condition was easily corrected by removal of the bone. He had been asked whether the diagnosis of cancer of the rectum was possible by means of the *x*-ray, and would say that such diagnosis could not be made by the *x*-ray alone. In fact he did not believe that a positive diagnosis of any condition whatever could be made solely with this. Additional evidence was always required, though the *x*-ray was of great service in the way of confirmatory proof.

Diagnosis of Thyroid Disease as Related to Surgical Treatment.—Dr. MARTIN B. TINKER of Ithaca, N. Y., said it had been a matter of surprise to him that it had taken so long for the profession to manifest an interest in the subject of thyroid disease. It was not his inten-

tion to take up the matter of treatment except incidentally. The question of operative or nonoperative treatment was one of great importance and interest, requiring the most careful consideration. Each case should be studied individually and, except where the condition was urgent, sufficient time be allowed to afford the opportunity to judge whether surgical interference would be advisable or not. During the past year, up to a few weeks since, he had seen some three hundred cases. Of these about sixty patients had been advised to wait and see what could be done for them by medical treatment, but it was his conviction that a considerable number of them would eventually come to operation. As to the character of operative procedure to be adopted, he did not believe that ligation alone would give cures. After operation it was certainly true that in certain instances fresh trouble developed, but in many of these this was due to the lack of proper after-care. Prolonged rest was of the utmost importance, and without this the surgical operation would not effect much. Postoperative care should really be maintained for from six months to a year, and results reported from three to ten years after treatment had shown in the vast majority of instances that the patients were doing well. When recurrences did take place, one of the best things to be done was to remove some more of the thyroid, and there was, he believed, very little risk of taking away too much. As to the heart changes occurring in hyperthyroidism, he had strong hopes that the electrocardiograph would yet prove of material service in the determination of these. Regarding the eye conditions, the careful study of a large group of cases would undoubtedly prove of great interest and practical value.

Dr. Walter L. Niles said that his viewpoint, as a result of his experience as an internist, was quite different from that of Dr. Tinker, a surgeon. In looking over the records of the Cornell University Medical College Dispensary, where a number of patients suffering from thyroid disease had been treated during the past eight years, he had been interested to find that about half of them gave as their chief complaint a "nervous heart," an expression no doubt obtained from their physician. Where the heart was unduly irritable one should always think of hyperthyroidism. In his experience there were three conditions from which thyroid disease had to be especially differentiated, namely, pulmonary tuberculosis, bacterial endocarditis, and neurasthenia. In the first the differential diagnosis was frequently difficult, and one might not be able to diagnosticate tuberculosis positively unless the physical signs were unequivocal. In such cases the *x*-ray was often of great value in localizing and determining suspicious areas. Another factor which made diagnosis difficult was the great sensitiveness of patients with hyperthyroidism to tuberculin. Bacterial endocarditis was not uncommon and was very frequently overlooked. Of special importance in the diagnosis were the fine pin-point petechiæ, most often apearing over the front and upper part of the chest. Of course, the demonstration of a bacteriemia was of great service, and for this repeated cultures were frequently necessary. Bacterial endocarditis might also be mistaken for tuberculosis. Neurasthenia, it was well to remember, was simply a complex produced by a great variety of conditions, a not uncommon one being hyperthyroidism. In considering the treatment of hyperthyroidism we found the greatest diversity of opinion, many surgeons inclining to operative interference, while most internists advised conservative measures. Excellent results had been reported by both, and hence the proper course must be a medium between these extremes. The difficult question was to decide which case should be operated on. The Beebe serum, a specific remedy, was of service in a very large proportion of instances. Personally, he believed that only those cases in which severe local pressure was produced, or which showed a tendency to malignant degeneration, should be operated upon. The most important point in any form of treatment was rest, and by this means alone a great many patients would be cured. In considering the advisability of operation we should always think of the end-results. A great objection to surgical procedure was that in many instances the symptoms returned, and in many others a mixed form, showing both hyper- and hypothyroidism developed. This was a most serious condition, for which little could be done, the patients usually dying in the course of a few years.

Dr. Harry Miles Imboden said that when formerly at an institution with Dr. Tinker he had seen quite a large percentage of nervous cases which appeared to be instances of exophthalmic goiter. In the diagnosis the *x*-ray was found very useful, especially where the goiter was intrathoracic. This would demonstrate the depth of penetration into the chest and the relation to the trachea. It showed the pressure of the thyroid on the trachea and it was of great service as well in differentiating it from a persistent thymus, aneurysm, or other mediastinal growth. In the substernal or intrathoracic form of goiter the thyroid was seen to be bilateral, cupshaped, and with the convexity pointing downward. A persistent thymus was triangular in outline, lower down than the thyroid, and with the base down. The appearance of an aneurysm was quite different from that of the thyroid. It was unilateral and the edges were sharply defined, and usually one could get pulsation.

Dr. Isaac Hartshorne said that regarding the eye symptoms in hyperthyroidism we were all familiar with the classical signs, namely, widening of the palpebral slit, failure of the upper lid to follow the eyeball when turned downward, the lack of convergence, and the sluggish reaction of the pupils in accommodation; also the epiphora and frequent weeping. The peculiarity of the eye symptoms was that they were not present in any definite regularity or any definite association with each other. Thus, some symptoms would be present in one case and others in another, while in a third there might be none. Probably epiphora was one of the earliest symptoms to appear, being due to pressure from the closely following exophthalmos. That we found exophthalmos in only from 20 to 25 per cent. of hyperthyroid cases was probably because we got the cases early in the course of the disease, and, as Dr. Tinker had said, the symptoms appeared late. The cause of the exophthalmos was still very uncertain. Most internists, he believed, held Müller's muscle, that small group of rudimentary muscle fibers spread out between the sphenomaxillary fissure and the supraorbital groove, responsible for this kind of exophthalmos. The theory of exophthalmos from irritation of Müller's muscle was, however, hardly tenable in these cases, since, as all other muscular tissue was in them weak and deficient in tone, it was scarcely reasonable to explain any one symptom as due to irritable contraction of muscular tissue. More likely the exophthalmos was due to an engorgement of arteries and capillaries in the orbit back of the globe. Exophthalmos of long standing was very obstinate to any kind of treatment, but was usually reduced by treatment of the goiter, medical or surgical. In early instances Dr. Tinker had reported one or two cases in which, after operation on one side of the neck, the eye on that side receded, while the other eye continued to bulge until the other side of the neck had been operated upon, when it also receded to an equal extent. Since, according to Dr. Tinker, convergence was lacking or deficient in 12 per cent., and the pupils sluggish in accommodation in 14 per cent. of these cases, and since we recognized a normal and definite relation between convergence, pupil activity, and accommodation, we should expect to find subnormal accommodation in hyperthyroidism. So far as he knew, this matter had never been worked up, and it would make an interesting study—of course, after careful cyclopegic refraction and also, as far as possible, eliminating presbyopia. There were usually no changes in the media, except scars from corneal ulcer, or in the fundus, other than an enlargement of the retinal arteries, which also could be seen to pulsate. Vessel pulsation in the eye was commonly venous, but in these cases was chiefly arterial. There were no signs of intracranial pressure. The inflammatory lesions appearing with exophthalmos, namely, chronic conjunctivitis and corneal ulcer, were due to exposure of the globe, and should be treated in the same way as when occurring under other circumstances. Corneal ulcers could easily become infected, and proceed to perforation and panophthalmitis, with destruction of the eye, or they might injure vision simply by diffuse or multiple opacities. A careful cyclopegic correction of refractive error was usually of great advantage to these patients. It would be well to refract with care all hyperthyroid subjects, not with the primary idea of lessening thyroid secretion, but for the purpose of stopping the leakage of nerve force through refractive error. The speaker said he was a firm believer in the conservation of nerve energy by the removal, so far as possible, of all sources of irritation, and it should be extremely helpful to these patients to conserve, by the removal of such sources of irritation as refractive error, that much more energy to combat the primary process. If the patient were to undergo thyroid operation, however,

it would be better to wait till after the operation to correct the refractive error. He understood that the Mayos were doing this in connection with and at the same time as the regular thyroid resection. As to their actual success, report would have to be made later. Osteoplastic resection of the outer wall of the orbit might be performed by either the method of Kronenlein or of Kocher, the latter's operation being less likely to injure the facial nerve and leaving a less noticeable scar. Simple tarsorrhaphy at the external canthus might also be done to diminish the abnormally wide palpebral slit. The fundamental significance of eye symptoms in hypothyroidism had yet been thoroughly worked out, as far as he knew, and he agreed with Dr. Tinker that an ocular study of a large group of these cases would bring out results of interest both to ophthalmology and to general medicine.

Dr. Alfred E. Cohn gave an account of a patient of Dr. Tinker who had been under the observation of Dr. Robinson at the Hospital of the Rockefeller Institute both before and after operation, the observation after operation lasting for about six months. Before the operation the area of cardiac dulness had extended to the right and left for a centimeter more than after it. Before operation the systolic blood-pressure was 135, and the diastolic 80, while the pulse-rate varied between 100 and 130. After the operation the systolic pressure gradually declined until it reached about 120, where it remained, but the diastolic pressure continued unchanged at 80. The pulse-rate also fell, and now varied between 80 and 95. Both before and after operation electrocardiograms were made, but these had yielded no information which could be regarded as useful. A larger experience, however, might prove of great interest. In order to reduce the pulse-rate in patients suffering from exophthalmic goiter Dr. Robinson had investigated the action of digitalis and of tincture of aconite. The doses of the latter employed were at first those usually recommended, but later he gave doses far in excess of these. It might be said, in general, that both these drugs failed to show any influence on heart-rate. Experiments were then conducted with the tincture of aconite in order to test its potency, and a detailed report of these would later be made by Dr. Robinson. Dr. James Mackenzie believed that the rapid rate of the heart in exophthalmic goiter depends upon the fact that the area of the peripheral circulation is enormously dilated. It was apparent, if this theory were correct, that an agent must be found which would aid in reducing the area of peripheral blood-vessels to normal limits. Should this be accomplished, one might expect the rate of the heart to become reduced.

Dr. Frank C. Raynor said that from his experience thus far he could not say that he had observed any relation between thyroid disease and affections of the throat. While many cases of such disease were associated with disease of the lymphoid tissue in the pharynx, equally as many were not. In one case of enlarged thyroid with pronounced tachycardia, in a girl of sixteen, very great improvement had followed the removal of adenoids and hypertrophied tonsils. He had also seen but few cases in which pressure symptoms had resulted from the growth. In one case there had been considerable mucus in the throat, but this he considered secondary to the circulatory disturbances. As to the use of drugs in goiter the red iodide of mercury, applied locally, and arsenic bromide, given internally, had seemed to him to be of some service. At a recent meeting in Brooklyn quinine hydrobromide had been highly spoken of, but he had not yet had the opportunity of giving it a trial.

State Medical Licensing Boards.

STATE BOARD EXAMINATIONS AND QUESTIONS.

Board of Medical Examiners of Maryland.

June, 1914.

ANATOMY.

1. Describe the gall-bladder and the biliary ducts.
2. Define synarthrodial, amphiarthrodial, diarthrodial joints, and give three examples of the latter.
3. Give the origin and distribution of great sciatic nerve.
4. Name structures contained in cross-section of thigh on a level with the beginning of Hunter's canal.
5. Give attachments, action and nerve supply of these muscles: Digastric, peroneus longus, biceps femoris, superior oblique (oculi) and pronator radii teres.
6. Name varieties of cartilage and state where each variety is found.
7. Give brief description of the lymphatic system.
8. General description of thymus body.
9. Practical examination.
10. Practical examination.

PHYSIOLOGY.

1. Name the forces concerned in the circulation of the blood, and describe how each acts.
2. Define protoplasm, and give properties of living protoplasm.
3. Describe the effects of starvation on the various body tissues.
4. (*a*) Give functions of the medulla oblongata. (*b*) Give functions of the cerebellum. (*c*) Give functions of the spinal cord.
5. Describe the functions of the skin, mucous membranes and serous membranes.
6. Describe the formation and functions of lymph and the properties and functions of bile.
7. Describe the muscular mechanism of digestion.
8. State what you know of the sources and distribution of the heat of the body.
9. Define secretion, excretion, absorption, nutrition, and state difference between external and internal secretion and give examples.
10. Give a general classification of foodstuffs and give examples of each.

ANSWERS.

ANATOMY.

1. The gall-bladder and bile-ducts. The *gall-bladder* is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage.

The *hepatic duct*, formed by union of ducts from right and left lobes, issues from the liver at the bottom of the transverse fissure. It passes downward and to the right in the layers of gastrohepatic omentum, having the vena porta behind and the hepatic artery on the left. It joins the cystic duct, the two forming the common bile-duct.

The *cystic duct* passes from the neck to the gall-bladder downward, backward, and to the left, to join the preceding.

The *ductus communis choledochus* or *common bile-duct* is the result of the union of the hepatic and cystic ducts. It passes behind the first part of the duodenum, in front of the vena portæ, with the hepatic artery on the left, between the layers of the gastrohepatic omentum, and, passing between the pancreas and second part of the duodenum, enters the small intestine obliquely a little below the middle of the descending part of the duodenum by an opening common to it and the pancreatic duct.—(From *Aids to Anatomy.*)

2. *Synarthrodial joints* are articulations which do not allow of any appreciable movement.

Amphiarthrodial joints allow of limited movement.

Diarthrodial joints allow of free movement; *examples:* elbow, shoulder, knee.

3. The *great sciatic nerve* arises from the first, second, and third sacral nerves of the lumbosacral cord. It supplies the hip joint and the biceps, semitendinosus, semimembranosus, and adductor magnus muscles.

4. *Structures contained in cross-section of thigh on a level with the beginning of Hunter's canal:* Skin, fascia, tensor vaginæ femoris, femoral artery and vein, profunda femoris, external circumflex vessels, superficial obturator nerve, external cutaneous nerce, anterior crural nerve, deep obturator nerve, small and great sciatic nerves, adductor longus, sartorius, gracilis, pectineus, rectus femoris, adductor brevis, adductor magnus, semimembranosus, semitendinosus, crureus, vastus internus, vastus externus, biceps femoris, and the femur.

5. Digastric. The posterior belly arises from the digastric groove on the internal surface of the mastoid process of the temporal bone; the anterior belly, from a depression on the inner surface of the lower

border of the inferior maxilla, near the symphysis. These two bellies are connected by a central tendon which perforates the stylohyoid, and is bound down to the greater cornu of the hyoid bone by a process of fascia. *Action.*—It raises the hyoid bone and depresses the lower jaw. *Nerve supply.*—The posterior belly is supplied by the facial; the anterior belly by the mylohyoid branch of the inferior dental.

PERONEUS LONGUS. *Origin:* Upper two-thirds of outer surface of fibula, and external tuberosity of tibia. *Insertion:* Internal cuneiform and first metatarsal bone. *Nerve supply:* Peroneal. *Action:* It extends and everts the foot.

BICEPS FEMORIS. *Origin:* Tuberosity of ischium, great sacrosciatic ligament, and linea aspera. *Insertion:* Outer side of head of fibula. *Action:* It flexes the leg on the thigh, and rotates the leg slightly outwards. *Nerve supply:* The great sciatic.

SUPERIOR OBLIQUE (OCULI). *Origin:* From inner margin of optic foramen. *Insertion:* Into sclerotic. *Action:* Rotates the eyeball on its axis. *Nerve supply:* The fourth crainal or patheticus.

PRONATOR RADII TERES. *Origin:* Humerus, just above the internal condyle, and from inner side of the coronoid process of the ulna. *Insertion:* Middle of outer surface of shaft of radius. *Action:* It rotates the radius upon the ulna, and assists in flexing the forearm. *Nerve supply:* Median nerve.

6. *Hyaline cartilage* is found in the nose, larynx, trachea, bronchi, synchondroses, symphyses, costal cartilages and articular cartilages. *Elastic cartilage* is found in the epiglottis and cartilages of the larynx.

Fibro-cartilage is found in interarticular cartilages, symphysis pubis, between the vertebræ, around the margin of the acetabulum and the glenoid cavity of the shoulder.

7. "The LYMPHATIC SYSTEM includes the lymphatic vessels and glands and the lacteals, and forms an important accessory to the blood-vascular system, collecting the transuded, unappropriated fluids of the body and the nutritive material derived from the food and conveying it into the venous system. It consists of two main trunks: The thoracic duct, and the right lymphatic duct; and five smaller trunks: The jugular lymphatic trunk, subclavian lymphatic trunk, broncho-mediastinal lymphatic trunk, lumbar lymphatic trunk, intestinal lymphatic trunk.

"Lymphatics have been found in nearly every organ and texture in the body except the brain, the spinal cord, cartilage, tendon, eyeball, placenta, umbilical cord, membranes of the ovum, hair, cutis, and the labyrinth of the ear. They appear to originate as fine capillary nets interwoven among the blood-vessels and proper elements of the tissues, or, more minutely, in the lymph, perivascular, and perineural spaces. In the villi they commence as closed, club-like tubes.

"The *lymphatic capillaries* are somewhat larger than the vascular capillaries and destitute of valves. Their main trunks pass through lymphatic glands lying in their course, before doing which, however, they divide into afferent vessels, which, on emerging, unite into a smaller number of larger vessels, the efferent.

"In structure, they are composed of three coats—the external fibro-areolar, middle muscular, and internal or endothelial and elastic.

"The *lymphatic glands* are generally situated in the course of the blood-vessels, lymphatic vessels, or lacteal vessels, being accumulated together in certain localities, as the neck, abdomen, axilla, etc. The lymphatic glands and vessels are named from the regions they occupy or the vessels they accompany, and consist usually of a superficial and deep set. Thus, we have cervical, axillary, mediastinal, lumbar, inguinal, etc., and the lymphatic vessels corresponding.

"The *lacteals*, or chyliferous vessels, are the lymphatic vessels of the small intestine, and differ only from the others in carrying chyle during digestion from the intestines to the thoracic duct."—(Young's *Handbook of Anatomy.*)

8. "The *thymus gland* attains its full size at two years, after which it gradually shrinks away. It is situated partly in the anterior mediastinum, and partly in the neck, reaching from level of 4th costal cartilage upward on trachea as high as lower border of thyroid gland. It consists of two lateral lobes with occasionally a middle connecting one. *Relations of each lobe in early life.—Anterior:* Sternum as low as 4th costal cartilage, origins of sterno-hyoid and sterno-thyroid muscles. *Posterior:* Trachea, pericardium, and great thoracic vessels. *Base:* Pericardium. *Laterally:* Pleura, sheath of carotid. *Medially:* Opposite lobe and side of trachea."—(*Aids to Anatomy.*)

PHYSIOLOGY.

1. The circulation of the blood is regulated in (a) *the arteries* by: (1) The elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

2. *Protoplasm* is the matter of which cells are made; it is the physiological basis of life, and consists of water, protein, lecithin, cholesterin, phosphates, chlorides, and other substances. Its constitution is unknown. *Properties of living protoplasm:* Irritability, or power of responding to a stimulus; power of movement; power of assimilation; power of growth; power of excretion; power of reproduction.

3. During *starvation*, the body loses weight, the various functions gradually become weaker, the body temperature first rises then falls, and death supervenes after the loss of about 40 per cent. of the body weight. The loss is not equally distributed among the various tissues, as the muscles and fat lose the most, then the bones, skin and liver, and (least of all) the heart and brain and spinal cord.

4. The *functions of the medulla oblongata* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of co-ordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

The *functions of the cerebellum* are: Co-ordination of muscular movements, and maintenance of equilibrium.

The *functions of the spinal cord* are: (1) Conduction of nerve impulses; (2) reflex action; (3) co-ordination; it also contains special centers which preside over definite functions.

5. The *functions of the skin* are: Protection, secretion, excretion, regulation of body temperature, special sense of touch, general sensation, absorption and respiration.

Mucous membranes secrete mucin; and *serous membranes* provide a lubricating surface to prevent friction.

6. *Formation of lymph:* There are three main theories: (1) Ludwig's theory, or the filtration theory, coupled with osmotic changes between the lymph and blood; (2) Heidenhain's theory of lymphagogues; and (3) Starling's theory of the permeability of the capillary walls. The subject is summed up by F. A. Bainbridge as follows: "Lymph formation is not a secretory process, but is brought about by purely physical processes, namely, filtration and osmosis; and the factors concerned in its production are (1) the capillary pressure, (2) the degree of permeability of the capillary walls, and (3) the metabolic activity of the tissues. There is no reason to suppose that in health the permeability of the capillaries alters, and therefore the formation of lymph is increased chiefly by variations in the first and third of these factors." The origin and composition of lymph, its situation and relation to the tissue cells indicate that its *function* is to provide the tissue cells with those nutritive materials necessary to their growth, repair and functional activities, and to receive from the tissue cells their waste products prior to their removal by the blood and lymph-vessels.

Properties of bile: Bile is a transparent, viscid fluid, bitter, with an aromatic odor, and an alkaline reaction; the specific gravity is about 1010 or 1011 for fistula bile, and about 1025 to 1030 for gall-bladder bile. It contains water and solids. The latter are bile salts (sodium taurocholate and sodium glycocholate), mucin, bile pigments (bilirubin and biliverdin), cholesterin, lecithin, neutral fats, and inorganic salts (NaCl, KCl, and phosphates).

The functions of the bile are: (1) to assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neu-

tralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

7. "The *movements of the stomach* are most conveniently studied by direct observation with the aid of Roentgen rays after the administration of a meal mixed with a quantity of oxychloride of bismuth. In these circumstances the organ is seen to consist of two parts, the axis of the larger portion being nearly vertical, and forming an angle with the smaller pyloric portion, which is again subdivided by a constriction into two parts, the pyloric vestibule and the pyloric canal. After the ingestion of a meal, the muscular walls of the body and fundus become tonically contracted. Waves of contraction occur in the pyloric portion, beginning about the middle of the stomach and traveling at the rate of about three a minute towards the pylorus. The stomach contents are propelled by these waves towards the pylorus, and if the opening is kept closed by the contraction of the sphincter, they return by an axial stream towards the body of the stomach. In this way complete mixture with the gastric juice is effected. As digestion proceeds and the food is brought into a more fluid state, the sphincter undergoes periodic relaxation, opening every few minutes to allow the passage of the semiliquid material into the duodenum. By the tonic contraction of the fundus and body, the food is little by little subjected to the action of the pyloric mill, and subsequently passed on to the duodenum; and as the contents of the stomach are thus gradually diminished in quantity, the organ becomes more tubular in shape, until finally, four or five hours after the commencement of digestion, the process is complete. The precise mechanism by which the movements of the stomach are originated and carried out has not been definitely ascertained. It is still an open question whether these contractions are myogenic in origin, or are due to a local reflex through the plexus in the muscular coat. In any case, the movements may be considered to be under a certain degree of control by the vagi and the sympathetic, the former having on the whole a motor and the latter an inhibitory effect.

"The *intestinal contents* are slowly propelled along the gut towards the colon, and at the same time they are subjected to a continuous mixing process. The onward movement is effected by waves of contraction which sweep along the muscular coat of the bowel, and constitute what is known as peristalsis. The mixing of the material in the intestine is brought about by ring-like or segmental contractions, which are not progressive in character. These movements may be observed in the living animal or person by the aid of Roentgen rays after the administration of a bismuth meal. They can also be observed directly, if the abdomen is opened in an animal immediately after it has been killed.

"The *peristaltic movements.*—Any mechanical stimulus, such as pinching the intestine, will set up a peristaltic wave. The normal stimulus is a bolus in the lumen of the gut, and it is for this reason that the indigestible material of vegetable food is of value in promoting peristalsis. There are two features characteristic of the peristaltic wave: First, it is preceded by a wave of relaxation which begins below the point of stimulation, the contraction wave itself beginning above that point. Second, it always travels in the aboral direction. If a segment of the intestine be excised and again stitched in position in a reversed direction, the peristaltic waves in the reversed segment will be opposed to those of the rest of the intestine, and partial obstruction to the passage of the intestinal contents will result. Peristalsis still occurs when all connections with the central nervous system have been divided, but it is abolished by painting the gut with nicotine or cocaine. We may conclude, therefore, that it is effected by a local reflex mechanism connected with Auerbach's plexus (the myenteric plexus) in the muscular coat, the stimulus arising from the presence of a bolus in the intestine, and depending upon either the stretching of the intestinal wall or the irritation of nerve endings in the mucous membrane.

"The *segmental contractions.*—These differ from the peristaltic waves in occurring regularly and rhythmically. When they are recorded by means of a balloon in the intestinal lumen, they are found to be most marked at the middle of the balloon where the tension is greatest. The result of such contractions is to subdivide any bolus over which the contraction takes place, and thus to bring about a thorough admixture of the intestinal contents. Both layers of the muscular coat take part in these contractions, as well as in the peristaltic waves, and as a result the bowel exhibits pendular or swaying movements. The segmental contractions have no influence in promoting the onward movement of the intestinal contents."—(Bainbridge and Menzies' *Essentials of Physiology.*)

8. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air: (3) the excretions—urine and feces.

9. *Secretions* are materials separated from the blood by special cells, and which serve some further purpose.

Excretions are materials which are separated from the blood by cell activity and discharged from the body, and are harmful if retained, or at least are useless.

Absorption is the process by which the food, after it has been digested, is taken from the intestines to the blood, so that it may be available for the nourishment of the tissues.

Nutrition is the series of processes by which the normal conditions of structure and function are preserved to the body; it is the balance between digestion, absorption and assimilation on the one hand and excretion on the other hand.

External secretions pass from the organ where they are secreted directly by a duct to the surface of the body or into the digestive tract.

Internal secretions have no duct to convey them, but they pass directly into the blood stream or lymph channels.

10. *Foods are divided into:*

I. Inorganic. { Water. / Salts.

II. Organic. { Non-nitrogenous. { Carbohydrates. / Fats. / Nitrogenous—Proteids.

Examples of each: *Carbohydrate*, sugar and starches; *Fat*, fat of meat, and butter; *Proteid*, flesh of animals, and white of eggs; *Salt*, sodium chloride, and calcium phosphate.

(*To be continued.*)

The Chondrosomes and Phosphorus Poisoning.—Azzo Azzi has made an important contribution to the study of cytopathology in the discovery of distinct changes in the so-called chondrosomes or thread-granules of the cells of the liver, heart, and striated muscles under the influence of phosphorus poisoning. In the fatty degeneration of the liver cells the chondrosomes undergo a change in contour and a loss in the capacity to take a stain. In the case of the heart and of the striated muscles there is a gradual disappearance of the chondrosomes synchronous with the deposition of fat droplets.—*Archivio per le Scienze Mediche.*

Schamberg's Disease.—E. G. G. Little reports the case of a patient aged 56 who had never lived out of Great Britain. He enjoyed good general health. He had no venereal disease; no varicose veins. His family history was unimportant; the only skin detail was that his father was said to suffer from psoriasis. The condition began twenty-five to thirty years ago with the patch on the left leg. On the right leg, where the patch was actually larger than on the left, the disease only showed itself about eight or ten years ago. Within the last few months the small isolated punctate lesions in the neighborhood of the larger patches began to appear. There was no lesion elsewhere than on the legs. The affected areas were moderately itchy, but showed no other abnormal sensations. Below the knee on each leg on the anterior surface there were large patches, 3 by 5 inches in area, of cayenne-pepper-like punctate deposits of pigment, so closely aggregated as to produce plaques of pigmentation, forming curiously angular shapes with sharply linear and sometimes serpiginous outlines. The general effect was that of a buff-colored tattooing of the skin. There was in addition to the pigmentation a slight degree of scaling.—*Proceedings of the Royal Society of Medicine.*

UTERINE FIBROIDS, MENORRHAGIA, AND RADIUM.

BY ROBERT ABBE, M.D.,

NEW YORK.

SENIOR SURGEON, ST. LUKE'S HOSPITAL.

UTERINE fibroids, associated with unusual or profuse and exhausting hemorrhage (menorrhagia), are of the submucous and mural varieties.

The immediate source of bleeding is from the hypertrophied endometrium, which is spongy and highly vascular, or from the open-mouthed vessels whose lumen can be seen to be open on the thinned out musoca spread over the rounded surface of a tumor which bulges into the cavity of the uterus. These are easily demonstrated when a fresh section of the uterus and tumors is made immediatcly after hysterectomy. A little pressure squeezes out blood from the open mouths of one or more vessels. Often times thorough curettage removes the weak vessels, hemorrhage ceases and sometimes does not recur.

More often hysterectomy has been needed to insure a cure. Medication is of not much avail, though internal administration of gallic acid, or local intrauterine swabbing, with a mixture of antipyrin and salol, often arrests severe hemorrhage.

It is a pleasure to add an agent so simple and powerful as radium for the control of this serious

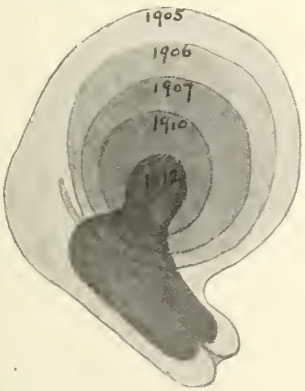

FIG. 1.—Case 1, Progressive reduction of fibroid tumor after the use of radium in the uterus; side view.

malady. But, best of all is the demonstrated greater effect of its reducing power and frequent cure of the tumor itself. It is quite probable that when the exact dosage of radium and its best method of application can be certified, it will be found to be a uniformly curative agent for fibroid tumors.

No simpler treatment can be conceived of than to introduce a thin, smooth, aseptic tube containing radium into the uterine cavity, leave it for one or

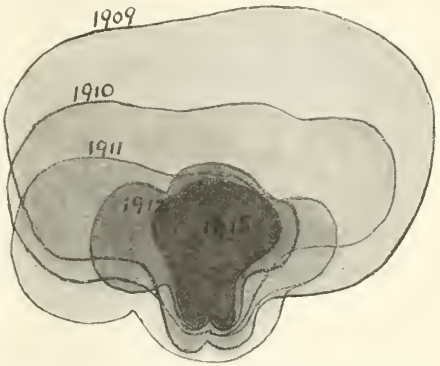

FIG. 2.—Case 11, Progressive reduction of fibroid tumors after exposure for four hours to 60 mg. radium in the uterus; front view.

two hours and watch improvement. Many patients are reduced to grave anemia, with waxy pallor, by prolonged hemorrhage, and the physician hesitates to offer the usual surgical procedure, especially when anesthesia is called for. In such types the radium treatment is a boon.

Its earliest known application was in 1905 for bleeding fibroids in one of my own cases.* My experience of the previous two years in using strong radium in many surgical conditions and in highly vascular naevi showed the truth of the claims of Wickham that obliterative endarteritis followed its use, and led me to hope that intrauterine vascularity would be altered by it.

In December, 1905, I was confronted by a case of extreme anemia from fibroid menorrhagia in which it seemed unwise to operate. The patient, a physician's wife, was forty-four years old. Under ether I curetted, and introduced a glass tube containing fifty milligrams of pure radium bromide for ten minutes. This would have produced a sharp reaction upon the skin. She progressively improved, menstruated normally, and recovered her health. In one year the tumor was perceptibly smaller. I again applied radium, sixty milligrams for fifteen minutes. During the following year I applied it again, on one occasion forty-five minutes and on another ten minutes, thus feeling my way along carefully to ascertain the safe and efficient

*Referred to in an address before the American Medical Association. See reports, 1906. Successful results reported by the author.—London *Lancet*, August 23, 1913.

dosage. The flow had ceased wholly and the tumor slowly reduced to an insignificant remnant. The patient has remained in perfect health ten years. The illustration (Fig. 1) is an exact reproduction of drawings from my note-book.

I ventured now to apply it for a longer period,

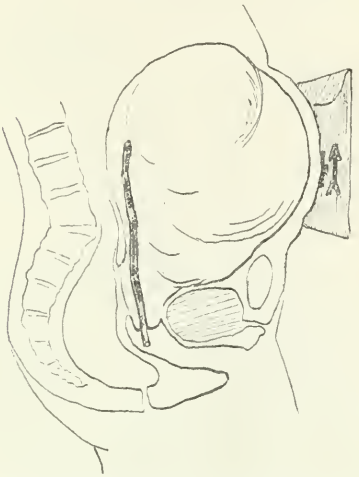

Fig. 3.—To illustrate radium radiation through large uterine fibroids. Photograph plate with lead devices external to the abdomen. Exhausting hemorrhage promptly arrested without curetting. Reduction of tumor follows slowly.

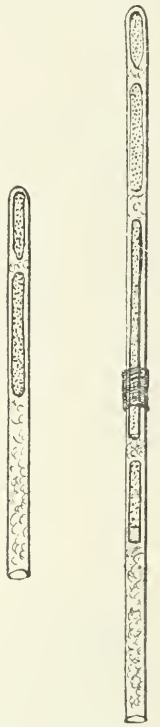
hoping to get quicker results. A lady of forty-nine years had refused operative treatment for growing fibroids which at last had caused increasingly severe hemorrhages, lasting sometimes three weeks. In June, 1909, I introduced into the uterine cavity sixty milligrams of pure radium bromide (forty radium element) and left it two hours without filter. On the following day I again introduced it farther than before so that it reached the fundus, the canal being a deep one. The tumor formed a broad mass extending from one iliac spine to the other, so that a finger could not be pressed down between it and the

Fig. 4.—Radiogram after 2 hours' exposure to 100 mg. radium element in utero, taken through 12 inches of uterine tumor and abdominal wall.

bone. The flow diminished and stopped in three months. A short flow came again, and I made one more application of one hour. In one year there was a marked reduction in the mass of tumor. The flow had stopped entirely. Each year the mass grew smaller until it became wholly insignificant. The patient meanwhile enjoyed perfect health, and a recent examination shows the tumor practically gone. The case is illustrated from accurate notes (Fig. 2).

Before speaking of later cases it is of interest to note the enthusiasm with which Drs. Kelly and Burnham have recently adopted this method in a recent report of twenty-one myoma patients.

It will surprise only those who have not witnessed the energetic action of radium to know that so small a tube of this powerful agent can exert a restraining and alterative force. The beauty of its application to so deep a cavity, unapproachable from within by *x*-rays, is manifest. But that its



A B

Fig. 5.—A, 55 mg. radium element in celluloid holder; B, 100 mg. in two holders joined together.

action resembles that of a Röntgen tube is worth a moment's explanation.

It has been recently demonstrated by Kroenig and Gauss that an intense, costly and almost dangerous use of penetrating *x*-rays from without, is capable of arresting menorrhagia and causing absorption of a fibroid tumor.

The gamma rays from radium, as also from the *x*-ray tube, are the deep penetrating force, but in themselves they do not effect the repression of tumor cells. This is brought about by the beta rays only. These are generated in the tissues through impact of gamma rays with all substances through which they are passing. The liberated beta electrons are immediately brought into action. These have been proved to be the efficient agent. (See Medical Record, Nov. 28, 1914.)

In addition to the intense far-reaching gamma radiation, we have also from radium an immense local exhibition of beta radiation close to the tube, which is absent in *x*-ray tube treatment. This has the tremendous advantage of local effect on the bleeding lining of the uterus. Its effect on the hypertrophied tissue is, to speedily bring about vascular blockade, lymph infiltration and cell retrograde, followed by restoration to healthy conditions.

To illustrate this great penetration, I have frequently placed upon the abdomen a photograph plate in dark paper envelopes, between which and the skin are fixed some lead devices which will be photographed by the radium resting in the uterus. To illustrate this effectively, the annexed sketch (Fig. 3) shows a recent large fibroid in a thick walled abdomen, on which was laid such a plate with lead devices stuck to it. The radium was left two hours in utero. Penetration of tumor and flesh was twelve inches. The picture on the photograph plate is shown (Fig. 4) and leaves no doubt of the all-pervading penetration of the gamma rays.

For years I have applied radium which is contained in very thin glass tubes, confining it in either vulcanite, silver, lead or gold holding tubes, to filter

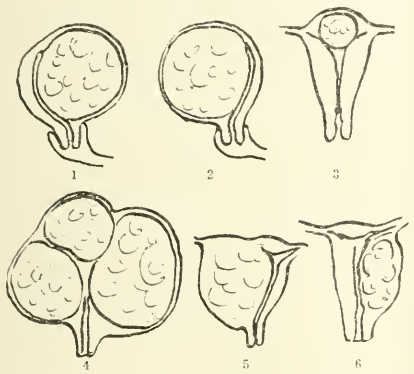


Fig. 6.—Types of uterine fibroid in which radium is curative. 1, Anterior; 2, posterior; 3, fundus; 4, general. 5 and 6, lateral.

out somewhat the soft beta rays, which are restrained by one-tenth of a millimeter of lead. But, better than all, are celluloid holders of the size and thickness of an ordinary goose quill. These offer little barrier to the passage of the beta rays, protect the radium, and can be sterilized. I have had them made for me by the thousand at slight cost, and do not use them twice. The length is ten centimeters, but two can be joined by wrapping adjoining ends with three or four turns of chiffon sealed by collodion (Fig. 5). Thus, in a deep uterine canal purified radium tubes can be held in contact with every part. It can be easily inserted in a tortuous canal where a straight silver holder might do damage. It is only necessary to compress the celluloid tube between the contained radium tubes and a jointed tube is formed adapted to the bends in the canal and can be safely pushed in.

In the case illustrated (Fig. 3) profound anemia from almost continuous hemorrhage was exhausting the patient. Without anesthesia, the cervix was purified by iodine, and a sound passed six inches into the cavity, which bled four ounces from the probing. This was at once checked by the smooth, long radium tube, containing fifty milligrams radium element, kept in two and a half hours. It was followed in four days by one hundred milligrams radium element in a very long tube which remained in for two hours.

This method seems to me to afford the maximum benefit with the maximum simplicity.

In the early intrauterine use of radium for fibroids, I felt the need of great caution and used moderate treatments at long intervals. Every new case treated has given me greater confidence in the use of larger doses and less frequent application. From my experience to date, I am of the opinion that speedy and wonderful results can be obtained by using from fifty to one hundred milligrams (radium element) in concentrated form in tubes placed in thin, smooth applicators without filter for one application of two hours. If, after two months, hemorrhage recurs, that may be repeated. The first concern is to stop bleeding. Incidental benefit comes from slow shrinkage of the tumor. Every six months examination will reveal its diminution. In some cases entire disappearance follows.

Thus far one may say that ten years' experience has demonstrated to me the persistence of good effect in menorrhagia of fibroids. The uniform reduction of tumors follows the prompt and permanent arrest of hemorrhage. I am inclined to think it wiser to obtain slow reduction by treatment as above indicated rather than by any more intense radiumization looking for extremely rapid disappearance. This caution may favor the preservation of a healthy uterine mucous lining which, to a woman desiring maternity, would be better than to risk cicatricial tissue which might replace a too violently altered membrane.

During twelve years my radium work has been divided in interest in all fields of surgery, and I have continued to offer myomectomy or hysterectomy to the greater number of cases presenting themselves, but I am now convinced of the efficacy and brilliant results of this painless and innocent use of radium in such cases as are here illustrated from my note books (Fig. 6). I regard it as the procedure of choice in all cases except pedunculated fibroids.

In all I have followed twelve typical and severe cases with the results demonstrated in this paper, and am satisfied the treatment of fibroids and menorrhagia has entered upon a new era.

RADIOCHEMICOTHERAPY; THE INTERNAL THERAPEUTICS OF THE RADIO-ELEMENTS.

By WILLIAM JAMES MORTON, M.D.,

NEW YORK.

FORMERLY PROFESSOR OF THE DISEASES OF THE MIND AND NERVOUS SYSTEM AND OF ELECTROTHERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In so far as the science of medicine relies upon the principles of radioenergy, the therapeutics of light, heat, and electricity, including the Roentgen ray, are fairly well established. But the therapeutics of the radioelements as relates exclusively to their internal administration as medicines offers a comparatively new and fertile field for exploration. Of these elements, thirty or more in number, radium, the most striking in its characteristics, has thus far claimed predominant attention. But radium is but one of the long uranium series and there remains

the collateral series of actinium and the thorium series in which mesothorium already rivals radium. Potassium and rubidium also are both fairly radioactive, though along lines not yet understood.

To this internal use of the radioelements the writer would apply the term *radiochemicotherapy* and would propose in the interest of an advanced therapeutics a brief survey of some of the medical and surgical possibilities inherent in them. To that end it will be useful to present them in tabulated form together with their types of rays and their period of half decay.

RADIOACTIVE SUBSTANCES.

TABLE I—URANIUM FAMILY OF RADIOELEMENTS.

Element	Rays	Period of Half Decay
Uranium I	Alpha	About 5,000,000,000 years
Uranium X_1	Beta, Gamma	24 6 days
Uranium X_2	Beta	1.5 days
Uranium II	Alpha	1,000,000 years
Ionium	Alpha	Greater than 200,000 years
Radium	Alpha, Slow Beta	1,690 years
Emanation	Alpha	3.85 days
Radium A	Alpha	3 minutes
Radium B	Beta, Gamma	26.8 minutes
Radium C	Alpha, Beta, Gamma	19.5 minutes
Radium D (radio lead)	Slow Beta	16.5 years
Radium E	Beta, Gamma	5 days
Radium F (Polonium)	Alpha	136 days
Actinium	No rays	?
Radio-actinium	Alpha, Beta	19.5 days
Actinium X	Alpha	10.5 days
Emanation	Alpha	3.9 seconds
Actinium A	Alpha	.002 seconds
Actinium B	Slow Beta	26 minutes
Actinium C	Alpha	2.1 minutes
Actinium D	Beta, Gamma	3 47 minutes
Actinium E	?	?

TABLE II—THORIUM FAMILY OF RADIOELEMENTS.

Element	Rays	Period of Half Decay
Thorium	Alpha	1,300,000,000 years
Mesothorium 1	Rayless	5.5 years
Mesothorium 2	Beta, Gamma	6.2 hours
Radiothorium	Alpha	2 years
Thorium X	Alpha	3.64 days
Thorium Emanation	Alpha	54 seconds
Thorium A	Alpha	0.14 seconds
Thorium B	Beta, Gamma	10.6 hours
Thorium C1	Alpha	60 minutes
Thorium C2	Alpha	Very short life
Thorium D	Beta, Gamma	3 1 minutes

TABLE III—OTHER RADIOELEMENTS.

Potassium Rubidium	Beta rays, 1-1000 of the activity of the beta rays due to an equal weight of uraoium.

Chemically, all the above radioactive substances are independent elements. They differ, however, from the other known elements in that their atoms undergo a continuous spontaneous disintegration by reason of a loss, in fixed ratio to each atom, of a part of its substance projected at great velocity—and termed a "ray." The residue, after loss of the radiated particle, becomes a new element, of new atomic weight, and new chemical and physical properties. It may be gaseous or solid. The rays are termed alpha, beta, and gamma, and possess individual properties of their own. Their discovery is due to the work of Becquerel, Lenard and Roentgen.

These facts are mentioned to point out that we must extend our horizon as regards the radioelements and must take into account not alone (1) the properties of the radioelement as a source of radiation, but also (2) its properties as a chemical.

These two properties are essentially dissimilar. They may act conjointly as when the element is used as a drug, which then exhibits its characteristic rays, or they may act apart as when the rays alone are utilized, as for example the application externally of the gamma rays of radium C or those of mesothorium.

The conjoint action, for which I am now asking consideration, we may well, as above said, term radiochemicotherapy, a new aspect of medical science forced upon our attention by reason of the discovery of the radioelements. I regard it as quite probable that ultimately radiochemicotherapy, namely, the internal use of the radioelements as medicinal drugs, will, by reason of its greater scope of general applicability, surpass in value anything now gained by the use of the rays from the exterior. For, employed internally, namely, as a drug, the element behaves, first, chemically by making the usual combinations in the various tissues, and second, when thus localized, even for a short time, exhibits at that point its effects due to its radiation. It is evident that, thus fixed within or in immediate contact with cells, by reason of nearness of action a small force may produce an effect as profound as, if not more profound than, a much larger force acting at a relatively greater distance. If the radioactive chemical has at the same time selective action for a given tissue or tissues, as have, for instance, the heavy metals, quinine, arsenic, iodine, etc., the chances for selective radioaction are much enhanced.

The writer of this article some years since conceived the idea so to fix and localize a metallic or other radioelement in cancer tissue as to obtain both the chemical and the radiation effects at the same time, thus supplanting and perhaps excelling the results obtained by the external use of the rays. To carry out this plan this paper serves both as an introduction and to lay the foundations for a practice in which he can already claim a very considerable success based upon a long series of chemical and physiological experiments still in progress.

External Use of the Rays.—As regards radium (radium C), available quantity and improved technique are slowly but surely demonstrating the transcendent value of this radioelement for the treatment of cancer. No means hitherto known except the closely related Roentgen ray has ever proved to be selectively deterrent or annihilating to the cancer cell's proliferation and life. Massive dosage and filtration of undesired beta and secondary rays insure successes not hitherto attained.

For external use, also, mesothorium is quite the equal of radium C as a source of beta and gamma rays. In the final triumph of external radium therapy it is no small gratification to the writer to recall that in 1907 in a comprehensive article[1] based upon some years of actual work in radium therapy, he published technique and results which may as well have been written today so far as regards success and detail except as to the point of filtration of rays, a modern improvement. Indeed, to the pioneers in more than a decade's work in external radium therapy the world over it must seem not a little amusing to see how the subject has apparently only recently been discovered.

But it is not intended in this paper to enter upon this branch of the subject. I believe we have now reached a point where external radium therapy rests upon a firm basis of scientific approval, and that therefore we may with advantage turn attention further afield, namely, to the internal administration of the radioelements. In this field the administration of radium emanation has already assumed a dignified importance and its practice is growing apace, while, both externally and internally, polonium, uranium X, thorium X, thorium B and D, actinium X, actinium D, and others of the thirty

new elements, have a power and a specificity uniquely their own.

Radiochemicotherapy or the Internal Administration of the Radioelements.—Radium emanation (radioactive water). Passing down the uranium series we arrive at radium metal, with a half period decay of 1690 years. A fixed ratio of its atoms in turn explode, throwing off at a great speed an alpha particle. The residue of the atom after the expulsion of this alpha particle is the emanation now suddenly taking on the form of a gas. The expelled alpha particles are helium, a monatomic inert gas, incapable of chemical combination. But inert as is the ejected alpha ray, helium, the residual emanation holds a vast potential of energy, exhibited both in itself and successively in the remaining members of the series. Thus, emanation atoms in turn throw off alpha particles and the residue becomes radium A, a metallic element of very short life. Next succeeds radium B, of life of about 27 minutes, and next radium C. Atoms of radium C are now torn asunder in the severest explosion of any occurring in the series. Alpha, beta, and gamma particles (rays) are shot forth, the alpha at high speed, the beta with nearly the velocity of light, capable of penetrating all metals, and the gamma similar to Roentgen rays, but 40 to 100-fold more penetrating. Some of the succeeding explosions of these retrograde transformations are tame in comparison. But they end in polonium (radium F) which, weight for weight, has an alpha ray activity that is about 6,000 times greater than that of radium.

From the foregoing it is obvious that radium-therapy is practically radium-emanation therapy, since from the emanation springs not alone its own alpha rays, but also, almost directly, the radium C, whose violent alpha, beta, and gamma rays provide the basis of our present radium therapy. And this emanation is peculiarly adapted to general therapeutics since it is absorbed by fluids and may be administered internally by the mouth, may be inhaled and absorbed into the blood stream by way of the lungs, or may be condensed in glass tubes, and for a brief period of time take the place of radium for external use.

From the time of the Romans the striking curative results arising from drinking or bathing in the waters of certain natural springs or spas have been recognized. Miners working in the uranium mines noted that they were free from rheumatism and other ailments. As the centuries elapsed the "Brunnengeist" or Spirit of the Springs became a household word to sufferers who drank their waters now known to have circulated through beds of ore containing radium, thus absorbing the gaseous emanation from crevices and chambers where it accumulated.

As regards the curative value of these springs, chemical analysis failed to give an adequate explanation. Having analyzed the waters of the Gastein Springs, Baron Liebig prophetically ascribed their healing qualities to electric effects. He spoke more truly than he knew, for the rays fundamentally act as an internal electrification of an order not hitherto practised in electrotherapy. And Burckhardt-Eble, in 1835, in a book on the subject of the curative results due to the waters of this same spring, after excluding the saline contents of the waters as having any part in the cures, wrote: "We therefore conclude that the waters contain a gas, the existence and classification of which will in due time be discovered and recognized as the acting substance."[2] The discovery came only in 1903. The gas was the radium emanation.

It is thus that nature and accident and prophecy often point the way to discoveries of the highest importance to the human race, for it is now established beyond question that the waters of these springs contain the radium emanation in varying but considerable amounts, and still further that this emanation, as now scientifically procured by laboratory methods, possesses healing powers far beyond the conceptions based upon earlier experience.

Since the emanation is a gas, it soon escapes from the water. Emanation water, removed from the influence of radium, loses its strength, one-half in four days, one-half of the remaining half in eight days, and practically entirely in one month. For this reason it should be drunk at its source, or, if bottled, soon after bottling.

The degree of activity of the radium emanation dissolved in water is expressed in terms of curies or in Mache units per liter. Avoiding details, we may simply say that the usual ionization current due to the emanation gas held in solution in a liter of water and expressed in terms of electrostatic units is, for convenience, multiplied by 1,000 to give the result in Mache units, and further that one curie is the amount of radium emanation in equilibrium with one gram of radium element. This quantity measured by the ionization method gives 2.67 million electrostatic units (0.89 milliamperes). Therefore, expressed in Mache units, one curie of emanation per liter would equal a strength of about 2,670 million Mache units. One microcurie is the quantity of radium emanation in equilibrium with one microgram (one millionth of a gram) of radium element. Therefore one microcurie (corresponding to one microgram of radium element) per liter equals a strength of about 2,700 Mache units. Here we reach terms easily comprehensible for comparisons and for exact dosage.

Internal emanation therapy offers problems differing from the external. In the latter the alpha rays, which constitute perhaps 90 per cent. of the whole, cannot penetrate the epidermis, but, employed internally, the alpha rays, powerfully ionizing, can exert their full and their especially differentiated effects. To this must, of course, be added the effect of the beta rays, and to a lesser extent that of the gamma.

Action of the Emanation.—The action of the emanation upon plant growth has been studied by various authorities. From it we may draw useful parallels to its action upon human beings. Julius Stoklasa,[3] using radioactive water from the springs of St. Joachimsthal (300-600 Mache units per liter, Franzenbad (150 Mache units per liter), and Brambach (1,700-200 Mache units per liter), saturated the soil of growing plants and noted the effects upon cell increase and growth. The results are so remarkable that I will produce them. It was found that with 96 Mache units there was a great increase in dry weight of the plants, which had been exposed to emanation during 46 days' growth, as shown by the following table:

	Radioactive Water, Gm.	Non-radioactive Water, Gm.
Pisum arvense	6.873	2.137
Lupinus augustifolius.	3.793	1.845
Vicia faba	12.887	6.009
Hordeum distichum	9.085	0.906

In other experiments (70 Mache units per liter) there was an increase of from 62 to 158 per cent. in the dry weight of the plants over the dry weight of control plants.

It must be equally noted that a certain increase of the emanation at first increased growth, but later on retarded it, as shown in the following table of results using buckwheat:

	Dry Weight of Plant
Inactive water	9.45 gm.
Water containing 30 Mache units	13.54 gm.
Water containing 60 Mache units	19.54 gm.
Water containing 300 Mache units	Bad effect

These results as regards dosage emphasize a generalization in respect to all radiation treatments, as well, indeed, as to many drugs, namely, that a certain relatively small dose stimulates cell action; a certain larger dose is noxious to some cells and not to others (selective action), and a still larger dose is destructive to all cells.

Again, Dr. H. H. Rusby, dean of the Columbia University of Pharmacy, has demonstrated practically in a series of elaborate experiments upon field crops covering hundreds of acres that radium (which means, of course, the radium emanation) is a wonderful stimulant to plant life. The increase in production in lettuce was 29 per cent., in cucumbers 35 per cent., in squash 35 to 44 per cent., in radishes 70 per cent., etc., etc., through a long list.

Dr. Rusby's experiments demonstrate that the entire plant, and more especially the root, becomes radioactive, and that this activity resides in the contained water of the plant. The roots absorb the radium emanation water from the soil and thus root crops especially benefit. From this general point of view we have a striking illustration of the mode of action of radium emanation water (as, indeed, of other radioactive fluids to be alluded to) when employed in human beings by actual drinking. The water, charged with the emanation gas giving off its alpha rays, and also continuously transmuting into radium A, B, and C, with their alpha, beta, and gamma rays, circulates in all the juices of the body and stimulates the cells to their normal healthy function, including the assimilation of food, which, as in the case of plant fertilizers, must be furnished in due supply. In the case of smaller animals to whom large doses of radioactive substances have been administered, it is possible to obtain a picture of the long bones through their direct action upon a photographic plate.

Effects Upon Human Beings.—It would far transcend the limits of this paper to enter upon this branch of the subject fully. To those interested a presentation of general results may be found in two articles by Dr. S. Saubermann of Berlin, and one by Prof. Paul Lazarus of Berlin.[4]

The progress of radium emanation therapy has been slow in this country, though established on a firm basis in Europe through the labors of eminent authorities such as Von Noorden, Von Neusser, Kraus, Paul Lazarus, Winternitz, Gudzent, Minkowski, Klemperer, Haubner, Saubermann, Mache, Curie, Laborde, Foveau de Courmelles, Finzi, the Radium Institute of London, and many others. Over a thousand papers on the radium emanation have already appeared.

The primary effect of the emanation treatment is, with little doubt, largely due to ionization produced by the alpha and beta rays. It is therefore fundamentally electrical. The activity of the various ferments of the body is increased. Chemical reactions become more active. This means an increase of the rapidity of tissue oxidation—in short, an increase of the sum total of all the chemical exchanges known as metabolism together with a corresponding elimination of waste products. As Saubermann says, "disturbed metabolism is nothing but disturbed fermentation."

The above is a broad view of the effects. Specifically the emanation causes peripheral blood vessels to dilate, thus reducing blood pressure, reduces the viscosity of the blood, thus facilitating its circulation, assuages pain to some degree, increases the amount of hemoglobin and the number of the erythrocytes, and while at first increasing, in larger doses diminishes the number of the leucocytes. It also has been claimed that it causes solution of uric acid. This on good authority is denied, though it is admitted that the nitrogen output (as urea) may be increased.

The emanation treatment has been used with success in rheumatism of the joints and of the muscles, in rheumatoid arthritis, in gout, particularly chronic gout, in neuralgia, sciatic and otherwise, in arteriosclerosis, in nephritis, in diabetes, in constipation, in locomotor ataxia, in anemia, and chlorosis. Favorable results in the above, as well as other diseases, are supported by eminent authorities.

Apropos of the effect of the emanation upon human beings both in a specific class of cases and in general, I quote from the authoritative source of the London Radium Institute as follows:[5]

"Arthritis Deformans.—The daily administration of 250 c.c. of radium emanation solution of a strength of not less than 1 millicurie per liter to patients suffering from this obstinate and painful and crippling disease is sometimes attended by very remarkable results. . . . Little or no improvement can be looked for in instances where cartilaginous or osseous changes are predominant, and the radium emanation solution is powerless to bring about the absorption of osteophytic growths or the loosening of fibrous or bony ankylosis. . . . When limitation of movement is due to periarticular fibrous thickening, considerable increase of mobility often follows on the taking of the radium water, and enables patients to perform actions, such as feeding themselves, brushing their hair, shaving, etc., which they may have been powerless to do for some months or even years. . . . Other favorable effects of the treatment are the lessening or disappearance of the muscular and articular pains, the grating of the joints on movement is not so marked, the muscles regain much of their lost tone, and the patient's general health is much improved. This is especially noticeable when the patients are suffering from anemia, the hemoglobin index being rapidly increased. . . . Much research work has yet to be undertaken to enable an accurate opinion to be formed of the manner in which radium emanation solution produces these results, as its action appears to be a multiple and highly complex one, but the reinforcing of the body ferments, the increase of tissue oxidation, and the dissolving uric acid are undoubtedly factors which contribute to its success."

One millicurie per liter represents 2,700 M.U. $\times$ 1,000 = 2,700,000 M.U. $\div$ 4 (250 c.c.) = about 700,000 M.U. daily. This is large dosage.

Probably the most important effect of the absorbed emanation is its action upon the ferments:

of the body as referred to above. The emanation increases autolytic fermentation (Neuberg), increases the activity of the peptic ferment (Bergell and Bickell), increases the activity of the pancreatic ferment (Braunstein and Bickell), of the lactic acid ferment (Richet), increases the solubility of uric acid salts (urolytic fermentation), increases the glycolitic fermentation (Deutelmoser and Saubermann) and increases the activity of diastatic fermentation (Edelstein).[2]

Another effect which I believe must be taken strongly into account is that upon the glandular tissue and upon the lymphatic organs. The glands of the skin and the cells of the testicles and the ovaries are especially sensitive, also the cells of the spleen and the bone marrow. A similar action upon the ductless glands is to be presupposed. These glands are interrelated in cause and effect, and upon

FIG. 1.—Five-gallon jar containing sixty pounds of Joachimsthal pitchblende and water. From the two quart bulb above, fresh water is introduced as fast as radioactive water, after leaching through the powdered pitchblende, is drawn out at the stop cock below. Thus no air enters the large jar and it is always sealed.

their proper condition depends not only the health, the temperament, the character, the power and capacity for accomplishment, but also duration of life itself. It has been said that "a man is as old as his arteries." We would change this and say that "a man is as old as his ductless glands." If his thyroid, his adrenals, his pituitary, and the others functionate properly the old age of today becomes comparative youth with the retention of physical and mental vigor. Always presuming that the dosage and selection of radioactive substances are properly adapted, it is entirely within the bounds of present clinical experience to set into healthy glandular function the entire system of glandular organs and tissue, thus rejuvenating the prematurely failing body.

"*Activators.*"—Apparatus for the production of radium emanation for the treatment of disease is at the present time both here and abroad being extensively pressed upon the attention of both the medical profession and the public by manufacturers and producers of radium. There exists a live interest in the subject. Perhaps the writer may be allowed to claim that in respect to radium emanation activators and the valuable medical results of radium emanation therapy he was not merely wise after the event, for he devised apparatus and put this method in practice in 1903 and published it in detail in 1904 and 1905.[3]

One main object of his early publication, however, was to present not alone the method as now adopted, but also what seemed to be then and what seems to be now to the writer even a better way of producing radium emanation water. This was to employ the natural radium ore, pitchblende, and by immersion to secure to the water the continuously emitted emanation. I employed a hundred pounds of the ore and produced highly radioactive water, substantiating this by careful analysis and report upon it by Prof. Geo. B. Pegram and Dr. L. V. Case, of the Department of Physics of Columbia University. I also reported in this article a case of a superficial rodent ulcer of the cheek cured by drinking the water and taking esculin for its fluorescent quality.

My one hundred pounds of pitchblende has been producing continuously radioactive water since 1903, and I have as continuously employed it therapeutically. The water is of an activity of 80,000 Mache units and upward, a very high figure and accounting for medical results not to be accomplished by smaller dosages. I am glad at last to be vindicated by the corresponding recent dosages adopted, as already referred to, by the London Radium Institute.

I find an advantage in using pitchblende to be that I obtain not alone the radium emanation and its sequent products, but also the actinium and possibly thorium emanations and their sequent products. I estimate that 100 pounds of the best selected and purest pitchblende may contain say 1/3 of a milligram of radium element per kilogram (2 lbs.) of ore. This would be equivalent to about 30 milligrams of radium element. Now, 1 milligram of radium element corresponds to about 3,000,000 Mache units. But the pitchblende, even though reduced to the size of fine sand, occludes a vast amount of the emanation in its own particles. Therefore the resulting concentration of the emanation per liter of water is reduced and must be arrived at by actual measurement. The same holds true of all activators. Radium sulphate, commonly used, yields to the water only about 2.5 per cent. of the total emanation produced.

It is, of course, highly desirable that radioactive water and activators offered for sale should be of sufficient strength. As we have seen, the radioactive value of radioactive water may be and is measured in terms of Mache units, just as the electricity we use and pay for in our homes or industrially is measured in terms of kilowatts, or as commodities are measured in terms of pounds or bushels. Clinical experience has now taught beyond question that, as regards animal life, there exists a remarkable lack of toxicity and a tolerance to both the radium salts and the emanation administered internally. Clinical experience has equally taught that a dosage high in Mache units is required to produce satisfactory results in serious diseases.

The Radium Institute of London has used a radioactive water of as high as 2,700,000 Mache units per liter. As already mentioned, the writer has been using continuously radioactive water of 80,000 Mache units, often running up to 2,700,000 Mache units. Most of the waters now offered for sale promise a radioactivity of about 2,700 Mache units per liter.

Recently a patient said to me, "I have been paying my druggist $1 per liter for my radioactive water and I suppose yours is the same price." Now, the druggist's water was 1,000 Mache units per liter, making the price of mine, at the druggist's rate, $80 per liter. I doubt if the patient comprehended the difference. This incident I relate simply to emphasize the one point, namely, that every successful treatment demands that every apparatus sold should be guaranteed to produce continuously a definite amount of emanation and that all radioactive water sold should likewise be guaranteed as to its radioactivity in Mache units. It is needless to say that the quantity should be large and not small—opinions may differ, but personally I should consider that 10,000 Mache units per liter should be a minimum.

Fig. 2.—Radiogram made by radioactive water. Exposure 30 minutes.

Finally, upon the basis of personal experience with emanation water since 1903, I agree entirely with Dr. Saubermann, who, in closing his address before the Roentgen Society of London, says: "I now conclude my lecture in the words of Professor Kraus, 'The continued existence and future of emanation therapy depend upon the use of sufficiently strong doses.'"

Internal Use of Radium Salt Solutions.—The waters of some natural springs, notably those of Kreuznach, contain small quantities of radium salts in solution; others contain only the emanation. In either event, radium acts, as has been said, by its emanation only. Therefore to inject radium salts intravenously or to give them by the mouth is to look to the emanation for therapeutic results. But objection has been made that the radium salts used internally, or their subsequent transmutation products, may exert a harmful action by accumulating and remaining in the body and thus exerting a continuous radioactivity to the detriment of the tissues involved. Personally, I have had a long experience with the internal administration of radioactive substances, particularly uranium X and thorium X, and I have yet to observe the least harmful effects. True, it has been claimed by Dr. Lazarus Barlow, of the Middlesex Hospital, London, and Professor Caan, of the Heidelberg Radium Institute, that normal tissue is radioactive, that the older the person, the more radioactive the tissue, that the tissue of a carcinomatous person is more radioactive than that of a healthy individual, and that carcinomatous tissue is more radioactive than normal tissue—all of which, in my mind, goes to show that not only is radioactivity a normal exhibit of universal matter, but that furthermore it selectively has a specific attachment to cancer tissue. This latter we know already from experience with external radiation, and it therefore affords us the best of hopes for securing a beneficial if not indeed a curative reaction in the case where we administer internally and in sufficient quantity any of the radioactive substances, radium pre-eminently.

I therefore see no objection to the internal administration of the radium salts. Certainly thus far no injurious effects have been noted from giving quite large doses by the mouth or intravenously. While small doses had been thus used in Germany and results reported, it remained for Dr. Frederick Proescher, director of the Pathological Laboratory of the Standard Chemical Company of Pittsburgh, Pa., to extend the method to much larger doses by a series of careful experiments upon the lower animals and upon man.[7] Cases thus treated by Dr. Proescher with from 100 to 200 micrograms during a period of more than a year have shown no injurious effects. In one case of leucemia almost three milligrams of radium element were given. As to a fatal dose for human beings, according to his animal experiments, a dosage of at least 50 to 60 milligrams would be necessary to show pathological changes in the internal organs, especially in the liver and bone marrow.

On the whole, Dr. Proescher advocates a dosage of from 100 to 200 micrograms intravenously, stopping the administration at a total of one milligram. It is fairly evident from these experiments that radium used internally is not as toxic as had been supposed. It would appear that the largest part of the radium is slowly excreted after acting both chemically and radioactively.

Thorium and Thorium X.—Thorium X may be obtained by any of the well-known methods of chemical separation. I usually precipitate with ammonia, evaporate to dryness, and volatilize the ammonium salts. The residue is intensely radioactive, due to the thorium X, which now may be reduced to solution with hydrochloric acid, neutralized, and arranged for dosage. By this method both the emanation and the "active deposits," thorium A, B. C and D, are retained in the filtrate. About fifteen pounds of thorium nitrate, which sells at about $5 per pound, will give (provided the mesothorium has not been removed) thorium X equivalent in activity to one milligram of radium element. Chemically metallic thorium and its insoluble compounds are non-toxic. The toxicity of the nitrate is low. Used by intravenous injection, thorium X in a dosage of 1,500,000 Mache units, within the first 24 hours, causes weakness and loss of appetite, followed on the next day by signs of general improvement. A case of fatal result after the injection of 5,000,000 Mache units has been reported by Professor Orth.[8] A dose of 1,000,000 Mache units is now regarded as entirely safe, though a period of two or three weeks should be allowed between injections.

On the whole, thorium X and its successive trans-

mutation products are decidedly more toxic than radium. But at the same time its clinical effects are more positive. It has a great affinity for the lymphatic structures and has also been most successfully employed in articular rheumatism, caus-

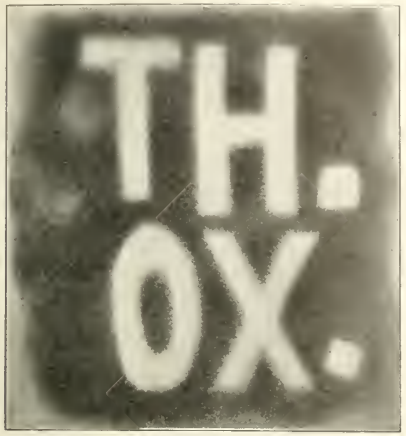

Fig. 3.—Positive of radiograph (autograph) of thorium oxide. Lead letters laid on light proof photographic plate and thorium oxide powder spread over them. 20 hours' exposure.

ing disappearance of pain and swelling and actual anatomical improvement of the joint. Its toxicity, or potency, is probably radioactive rather than chemical and possibly due to selective action to some extent.

The emanation may be driven from thorium oxide by heat and inhaled. This method I employed extensively some seven years ago, but with no pronounced success in any direction. I now prefer to give a thorium X solution by the mouth, arriving gradually at a cumulative effect. In this manner the emanation, whose half period is 54 seconds, makes one complete blood circulation, remaining at least long enough to leave its disintegration products behind it. The emanation can be demonstrated in the expired air and in the urine for five or six hours after administration of a single dose. Thorium X is soluble in physiological salt solution, and because of its short life must be used soon after preparation. Its principal ray product is the alpha ray, as no beta and gamma rays of importance come into play except during the brief life of thorium D. Clinically, keeping in view the idea of specificity of the rays, to be alluded to later on, I depend upon thorium X solutions for an alpha ray effect and upon uranium X solutions for a beta ray effect, administering in each case by the mouth.

Thorium X, though expensive, is not as expensive as radium. It has a wide range of therapeutic usefulness. For details as to the chemical properties and activities of the radioproducts of thorium, see McCoy and Viol[7] and Soddy.[8]

Uranium and Uranium X.—Uranium, unlike radium, actinium and thorium, has no emanation. It emits alpha rays and the residue becomes uranium X, next in the order of disintegration downward through radium to polonium. All uranium salts contain uranium X from a minimum to a maximum, according to the age of the salt. Freshly prepared, the amount is almost nil; in 24.5 days half value is reached, and in six months the full value of equilibrium is nearly obtained. The peculiarity of uranium is that it gives forth highly penetrating and highly ionizing beta rays about equal in intensity to those of radium C. To these beta rays is due the strong photographic effect of uranium and its salts. Its gamma radiation is very feeble and negligible. Uranium X may be chemically separated from uranium by any one of several methods described by both Rutherford and Soddy. In uranium X I see a specific agency for internal use of the beta rays alone. In the interest of future and accurate internal radiotherapy it seems to be important to use a single and specific ray, thus avoiding what may be termed the "shotgun" dose of emanation carrying alpha, beta, and gamma rays. Most assuredly in the latter case the alpha ray effect and the beta ray effect must conflict, since the one is of atomic proportions carrying a positive charge and the other a subatomic particle or electron, 1/1700 of the size of the first and carrying a negative charge, if, indeed, it is not itself negative electricity. The same argument in favor of a distinction as to the action of alpha, beta, and gamma rays applies to thorium, where in thorium B and D we have powerful beta rays with some gamma, but no alpha. To the ray effect must be added that of the chemical constitution of the element. Uranium as a chemical may be safely given in a dosage of from one to five grains three times daily.

Potassium and Rubidium.—It is noteworthy that as regards the therapeutic use of these elements, no attention so far as I know has yet been paid to their comparatively recently discovered radioactive properties. They and their salts have been found to exhibit two new and specific types of beta ray radioactivity, though it is considered doubtful at the present time whether we have to do with atomic disintegration of the type now established for the other radioelements. All the potassium salts show a beta ray activity of about the 1/1000 part of the beta ray activity of uranium. Rubidium exhibits

Fig. 4.—Same as Fig. 3, employing thorium nitrate powder; the solution acts in the same manner. 20 hours' exposure.

a beta-ray activity similar and yet distinct from that of potassium. Actually the activity of rubidium is very much greater than that of potassium, though the potassium beta ray is about nine times more penetrating than the rubidium beta ray. The

rays are about as penetrating as those of uranium X and are easily deviated by an electric field.

No chemical element has a more permanent hold upon the confidence of the medical profession than potassium and its various salts, particularly the iodide. The sale of potassium salts weight for

Fig. 5.—Positive of radiograph (autograph) of uranium X solution as at first obtained. Paper wet with the solution and dried is laid upon a light proof photographic plate. 20 hours' exposure.

weight probably exceeds that of any other drug in the Pharmacopœia. The action of the iodide of potassium has never been explained. Why use the potassium salt so efficiently in syphilitic affections and find no use for the sodium iodide in the same disease? May we venture the answer that its medicinal value is due to its radioactivity? A radioactivity of a degree of 1/1000 part of uranium element of equal weight is an energy not to be regarded lightly if we take into account the concomitant circumstance that solutions of potassium salts invade not alone the blood but also all the juices of the body. Each cell of the body enters into osmotic relation with the salt solution and takes to itself or gives up to the solution some of its identity at the moment.

And what shall we say of the numerous pharmacological and therapeutic interpretations of uranium and thorium salts with which our text books abound, comprising as they do extensive results of experimentation upon the lower animals and experience in their use with human beings? Obviously, a great, if not a preponderating influence, in the results reported must have depended upon the enormous ionizing effects of the uranium X and the thorium X contained in the drug at the moment of administration. For if the uranium salt, say the nitrate, had been freshly prepared within a few days of its use, it would be non-radioactive, whereas the same specimen of the salt, laid aside for 24.5 days to allow of the accumulation of a one-half value of uranium X would be very powerfully radioactive. Had Becquerel happened to have used a freshly prepared salt of uranium instead of a crystal of uranyl potassium sulphate long in his possession—in which, therefore, uranium X had had time to reach its equilibrium, we should probably never have heard of the Besquerl rays (uranium X) and also probably the incentive to Prof. and Madame Curie to search for radium and its rays would have passed by perhaps for a long time. Indeed it is remarkable how great a part accident, or shall we say Providence, plays in human affairs. Thus it is with the therapeutic action of the potassium salts. Accident leads to its true interpretation.

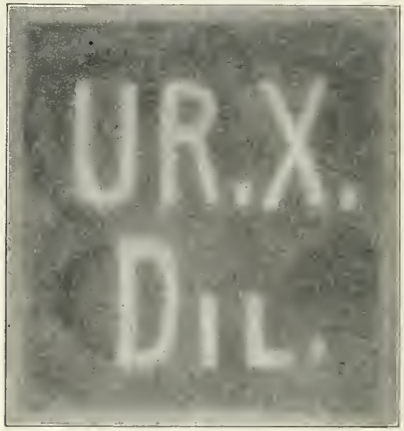

Fig. 6.—Same as Fig. 5, but diluted for internal administration by the month. 20 hours' exposure for comparison. Of these radiographs it may be observed that just as the medicine writes its own autograph on a photographic plate, so likewise it writes upon the human body into which it is taken.

Rubidium, like potassium, has been found to be a valuable therapeutic agent. Its bromide and iodide salts are very soluble in water and are well borne by the stomach. In ordinary tests of the salts of rubidium for radioactivity, its type of beta rays is absorbed by the salt itself to a greater extent than are the beta rays of potassium, owing to the higher penetrating power of the latter. Hence the deduction that the actual radioactive processes of rubidium in solution are greater than those of potassium. We may therefore draw the conclusion that rubidium deserves more therapeutic attention than has thus far been accorded to it. In radiochemicotherapy at all events it may, together with potassium, claim fellowship with its more powerful prototypes among the radio elements.

Specificity of Radiation Treatment.—The rays upon which we rely to produce therapeutic effects, whether externally projected against tissue, or internally projected in the midst of tissue, as by Internal administration of the individual radioelements are the familiar alpha, beta, and gamma. Each element of the thirty, in disintegration, gives off one or all of these rays. So different is one type from another that it must be concluded, and in a large measure it has been demonstrated by actual experiment on living cells, that their therapeutic effects differ even though they have many properties in common. The alpha rays are positively charged atoms of helium shot forth with a velocity of 12,000 miles per second, *i.e.* about 1/15 the velocity of light. Each alpha ray is a distinct ion—a helium ion. The particle has 6,800 times the mass of a beta particle, and moves with less speed, hence it is less capable of penetrating substances. It is stopped (absorbed) by 7 cm. of air, 1/20 mm. of aluminum, or practically by a sheet of paper, and yet it imbeds itself in the surface of glass and

strikes crystals of zinc sulphide with sufficient violence to cause scintillations of light. The alpha particles in fact constitute about 90 per cent. of the total radiations of alpha, beta, and gamma. It is shown (Rutherford) that the alpha rays "play a far more important part in radioactive processes than the beta rays, and that the greater portion of the energy emitted in the form of heat and of ionizing radiations is due to them." In external radiotherapy, owing to its comparatively weak penetrating qualities, this vast store of energy of the alpha particles is of no avail whatever; in fact, owing to the "burning" effects upon superficial tissue the rays are stopped by adequate filters. But the situation is reversed in internal radiotherapy where the intense physiological effects of the alpha rays have full play.

The beta ray is a negatively charged particle of a mass equal to 1/1700 that of an atom of hydrogen or 1/6800 that of an alpha particle; its velocity is that of light. Owing to this velocity and its small size it has about a hundred times greater penetrating power than the alpha ray. It is a swift cathode ray. The beta rays of radium are absorbed by about 5 millimeters of aluminum or 2 millimeters of lead. The beta and the gamma rays, while feebly ionizing as compared with the alpha rays, have a strong photographic effect, the gamma being feeble in comparison with the beta, and the alpha feeble in comparison with both beta and gamma. On the whole the beta ray is a very powerful ionizing agency.

The gamma rays are analogous to, but more penetrating than the x-rays. They are from 10 to 100 times as penetrating as the beta rays. In their flight of projection they produce beta rays all along their course, and it is more than probable that their ionizing effect in gases and their physiological effect in the treatment of disease is due to these beta rays. Under exposure to either alpha or beta rays glass turns of a violet or a blackish color. This I note continuously in the case of glass bottles, in which I dispense a solution of radioactive water for internal medication.

Therapeutically it is not reasonable to suppose that an alpha particle of large mass with a positive charge would have the same effect as the negatively charged beta ray particle of subatomic dimensions. Already clinical evidence is accumulating to show that such is not the case. This evidence need not be detailed here. In a recent communication, Dr. Robert Abbe[10] having devised a special apparatus for the separation of the rays by the well-known property of magnetic deviation, submitted both plant and animal cells to their more or less prolonged action and arrived at the conclusion that "separated beta rays from radium are demonstrated to be the efficient force most active against living cells." In this opinion he is undoubtedly at one with other observers. His accomplishment is to have demonstrated the opinion to be fact.

In internal radiotherapy this statement must be modified, owing to the far greater quantity of the alpha rays in ratio to the beta and gamma, and their peculiarly active ionizing effects, both of which qualities do not come into play in external radiotherapy. To the beta ray must be allowed its due quota of effect, but obviously the preponderating rôle will be played by the alpha ray. During a series of clinical experiments conducted now for over a year and still in progress, as to the relative influence of the alpha and beta rays administered internally, I have noted a marked difference in their effects. This is especially true as regards cancer, especially when there exists a broken down area which may be studied visibly and tested as to its secretions. I use uranium X as a source of beta rays and thorium X and radium emanation water of about 100,000 Mache units as a source of at least predominating alpha rays. To administer pure alpha rays would require the use of polonium or radium F which gives off only alpha rays and whose half period of decay is 136 days. We are hopeful that this test of polonium may soon be made, for already certain experiments have shown that certain effects are due to alpha rays alone. For instance, Altmann's granules, in healthy tissues submitted to all the rays, have been caused to disappear, but this does not occur when beta and gamma rays only are used.[11]

The above facts relate to the question of specificity of the rays themselves. But in radiochemicotherapy it becomes necessary, as has been said, also to take into consideration the chemical nature of the radioelement itself. Briefly, these elements are metals or gases. Radium element is a metal of the group of calcium, barium, and strontium, highly unstable, forming an oxide and a nitrate and ultimately a carbonate, in air. It is obtained in the form of its salts, the bromide, chloride, sulphate, and carbonate. Among the alkaline earth metals, it resembles barium most in its reactions. Uranium and thorium are long recognized metallic elements. The chemistry of the radioelements constitutes a most complex problem. Many of the elements as yet cannot be chemically separated one from the other and yet are known to be dissimilar by means of other equally reliable methods of examination. For instance, thorium and radiothorium are chemically identical and inseparable, but mesothorium, which comes between, may be easily separated from the other two. Uranium X chemically resembles thorium.

The following groups possess nearly the same electrochemical properties:[12] Radium, Thorium X, Actinium X. Radium B, Thorium B, Actinium B. Radium C, Thorium C, Actinium C. Thorium D, Actinium D.

Thorium, radium, and actinium produce radioactive emanations, each one step in the series of downward disintegration, and each capable of being condensed. Therapeutically it is believed that this gas acts as a catalyzing agent activating the body ferments. Curiously enough, while the emanation is an inert gas, its next radioactive successors ("the active deposit") are metallic, soluble in acids, volatilizable, and mechanically distributable.

That a gas, namely radium, actinium, or thorium emanation, may be dissolved in the blood stream and there change itself into a succession of metals, all, both gas and metals, highly radioactive and each capable of selective tissue combination, is surely a therapeutic thought of high interest and novelty. Or that radium, uranium, thorium, and other radioactive salts administered internally and medicinally shall undergo successive protean changes, jumping, so to speak, from element to element, and yet always shooting their rays into tissue, is calculated to inspire the idea that internal medicine yet possesses a wondrous field for investigation. Yet such is the invitation extended by radiochemicotherapy. These problems are of the utmost complexity, but they will be unraveled thread by thread from the tangled skein. Scarcely in decades

shall we know the promise and meaning of radiochemicotherapy.

In cases of cancer I have succeeded in producing both an arrest and a retrogression of the disease most decisively by the administration of the alpha and beta rays, both by the mouth and by subcutaneous injection, paying attention to the selectivity of the radioelement producing these rays respectively. The ultimate outcome of this line of progress must be reserved for another article to which this one is necessarily introductory.

In the various other diseases already referred to, I am finding that the progress already reported upon by many observers may be greatly enhanced by paying less attention to empirical results and paying more attention to a therapeutic selection of such radioelements as afford a specific action from both their chemical and their radiation qualities.

In conclusion, the proper preparation and administration of these radioactive substances constitutes one of the most subtle and refined branches of therapeutics, and it is to be fervently hoped that in the interest of general medical science and practice, some of our research laboratories will devote attention to the subject.

Summary.—1. Radiochemicotherapy is the combined therapeutic effect of two independent properties coexisting in a single chemical element, namely, radioaction and chemical action, both influenced by selectivity (specificity).

2. Thirty or more new elements have become known within a few years, of which only two, uranium and thorium, were previously known therapeutically, and these two not as radioactive, but merely as chemicals.

3. All of the thirty are radioactive and therefore produce therapeutic effects comparatively new to medicine.

4. All present a differing chemical constitution and therefore a different therapeutic action from a drug point of view alone.

5. From a radioactive point of view, all may be viewed as producers of either a positively charged or a negatively charged particle or ray, viz., alpha or beta.

6. That these rays affect human tissue in a remarkable manner is known and assumedly the action of a positive charge and that of a negative charge should be essentially different. This gives rise to a hope to establish in the future a specificity of action as between the two.

7. Already these radiations have established themselves, together with their congener the *x*-ray, as the sole agency which has specifically caused retrogression and repression of the growth of cancer.

8. This success by means of application from the exterior promises success by the use of the same rays introduced interiorly by medication in the blood and lymph streams.

9. In radiochemicotherapy the alpha rays, avoided in external radiotherapy, become of the highest importance, since in radioactive processes the greatest portion of the energy emitted in the form of heat and of ionizing radiation is due to them.

10. The radiations due to the radioelements used as medicines exert a profound and favorable effect upon the processes of metabolism. They are therefore indicated in a large number of diseases due to faulty nutritional processes, such as gout, rheumatism, anemia, etc.

11. Comparing the present success of external radiotherapy to the reasonable expectations of internal radiotherapy, the writer is of the opinion that the latter will in time far outstrip the former in successful medical service to the human race.

12. Radiotherapy in its fulfillment and radiochemicotherapy in its embryo are illustrations of the thought that the scoffs of yesterday are the medical practice of to-day, while those of to-day will be the practice of to-morrow.

13. In particular, in this line of work designated by the writer as radiochemicotherapy, it has been his aim to treat cases of cancer by causing a metallic or other radioelement to become "fixed" in the cancer tissue as iodine, for instance, becomes fixed in thyroid tissue and there exert a prolonged and intimate radiation effect, the more effective by reason of being able to utilize the highly ionizing alpha rays.

THE EFFICIENCY OF RADIOACTIVE WATERS FOR THE CONTROL OF FAULTY ELIMINATION.*

BY C. EVERETT FIELD, M.D.,

NEW YORK.

WERE it not for the fact that I have been assigned to speak to-night on radium, I feel that I should much prefer to detail my own personal observations as they relate to the delightful bit of nature's wonderland, located here in Saratoga. I could recount a knowledge of the healing powers of your waters, a tonic influence of your atmosphere, and tempered climatic conditions which, combined with the natural beauty of your surroundings, have made you famous in times that are past. Every metropolis as

*Read by invitation before the Saratoga County Medical Society at Saratoga Springs, N. Y., January, 15, 1915.

well as cross road hamlet has a reason for its very existence and I will venture the opinion that as a natural health resort, there is no spot on earth that has a clearer right to its title than Saratoga.

Before biblical times certain of the Roman Baths presented waters that were heralded to give forth mystic cures. The famous spas of Germany date their cures back to the feudal age. Here in America, tribal history among our Mohawk Indians recalls them journeying hundreds of miles to sojourn a season at Saratoga, to drink from its springs that which relieved their pains and brought new vigor to their bodies. The mysterious power and supernatural force which brought about the fabled cures was never hinted at, until, following the example of those who have studied the great foreign spas, we are hoping to ascribe to radium at least some of the peculiar virtues of these waters. The great hidden laboratory within the earth is awakening the scientific world to a greater appreciation of one of the most valuable agents of the healing art, Hydrotherapy.

That Saratoga has been blessed by hundreds of fountains, the component elements of which have been recognized, analyzed, and approved as especially adaptable to the relief and cure of chronic diseases, is known to you all. That Saratoga has carbonic springs not to be excelled in the world, is placing gems in the crown of the Empire State. With all this, however, we are not to forget another element of Saratoga's prominence—she has, what many of the great spas in the Old World have and that which others have not—all of Saratoga's springs are radioactive and several actually are solutions of the radium deposits deep down in her loins.

To-day the world at large is tremendously interested in radiumtherapy, and scientific effort in many different research stations is busy checking up its deductions on clinical achievements. It is most fitting then that we should consider for a little while just what radioactivity of the waters means; what are its possibilities in the relief of disease, and how can it best be administered?

That radioactivity as applied to the waters is a potent factor in therapy is evidenced by the fact that the most renowned spas of Europe are those which are found to be of highest radioactivity—that the saline, ferric, and carbonic principles, however, are equally important in eliminative treatments must be immediately granted. Hydrotherapy, no matter what its form, can best be appreciated by a complete understanding of its physiology. It is fitting that we have a clear conception as to the properties of one of hydrotherapy's most potent agencies, radioactivity. Not in many decades has the world held a theme of such universal interest as radium.

Radium was first isolated and named by Madame Curie in 1898. During the first five years but little was learned from this new element and insignificant was the advance made in its application in medicine until it was recognized as one of the basic factors of the healing springs. In nature, radium is found in close association with uranium ores, so minute are its quantities, however, that a single ton of carnotite, which is one of the uranium bearing ores, must be treated by over four tons of chemical solutions carried through hundreds of processes of recrystalization, over a period of nearly four months, and as a result we secure a tiny speck of a grayish-brown powder about the size of a pin head, which contains about two milligrams of radium element. When once obtained this small speck of radium evidences for a half period lasting about two thousand years the most remarkable liberations of energy known to man, and its entire life will not have been spent much short of eighteen thousand years.

Radium owes its energy to some unknown disruptive force, within each atom of the element, which results in the spontaneous disintegration of the atom accompanying the emission of the rays. These manifestations are commonly known as alpha, beta, and gamma rays, which are widely diverse in their type and power of penetration. In such a paper it will be impossible to give time to their discussions other than to quickly outline their general character. With the disintegration of radium we have produced constantly a liberation of alpha rays and emanation. It is the latter substance, a radioactive gas, that we are most interested in for the treatment of diseases of faulty elimination. Alpha rays are atoms of helium, charged with positive electricity. Beta rays are negatively charged electrons. Both alpha and beta rays exhibit marvelous powers of energy almost beyond conception. Alpha particles are shot out into space by an explosive force that drives them at a speed of 12,000 miles per second, while the beta rays have a velocity of over ten times the speed of alpha rays and nearly one hundred times their penetration. Gamma rays are defined as an ultraviolet light of exceedingly short wave length which penetrate opaque matter and excite peculiar phosphorescent phenomena in certain other elements. A small specimen of radium will cast its gamma rays through several inches of lead or six inches of battleship steel without effort. It is the beta and gamma rays that are used in the destruction of cancerous tissue.

Emanation is a gas which causes a phosphorescent action upon glass within which it is contained. It is readily absorbed by waters, oils, and innumerable other substances. Von Noorden on emanation states, "In contradistinction to all other forms of electrotherapy we possess in the radioactive substances means of carrying electrical energy into the depths of the body and there subjecting the juices, protoplasm, and nuclei of the cells to an immediate bombardment by explosions of electrical atoms. We may, therefore, designate this internal treatment with radioactive substances, internal electrotherapy."

As in the treatment of cancer the conservative operator recognizes radium as simply one more knife in his instrument cabinet, so we prefer to urge the use of radium and its emanation in internal medicine. It is only one of the therapeutic agencies that nature's laboratory has given us for the cure and alleviation of the miseries of mankind.

Although it is my privilege at this time to discuss the use of radioactive waters for the treatment of faulty elimination, it is my purpose to make it very clear that I am to discourage the thought that radium is a panacea for all the ills of human kind, or miraculous as a rejuvenator. We must recognize in this element and in the energy it imparts simply one remedy which when scientifically administered in conjunction with other recognized measures of treatment assures us of a definite activation of the body's excreting organs and its ferments. I think it is fairly well established that emanation physiology is largely dependent upon its catalytic action (as a contact body it controls chemical action, but is itself not consumed).

In the light of our present understanding certain of the physiological manifestations of emanation due to physical and chemical effects are clearly evidenced as serviceable in many of the cardiovascular degenerations, in improving general metabolism, influencing the solubility and absorption of uric acid, and in stimulating the body ferments. We have yet to learn much as to the definite process by which emanation exerts its beneficent influence. Cardiac activity is lessened and blood pressure is lowered, and in company of vasomotor excitation we have a dilatation of the blood vessels. The coagulation period of the blood is materially shortened yet the viscosity is diminished. It markedly increases the red blood corpuscles and produces leucocytosis of temporary duration. A lasting tonic effect is exerted.

Abundant literature detailing the exhaustive biological and physiological research of worthy observers is at hand and can be accepted, especially that which pertains to metabolism. The careful and accurate findings of such workers as von Noorden, Gudzent, His, Deutelmoser, Klemperer, Falta, and von Neusser tend to substantiate much of the true physiology of emanation.

Enormous effort has been made in the application of these physiological principles in therapy and as a result we find each year hundreds of thousands of human sufferers making their pilgrimage to those vast centers of healing in Germany, Austria, and France, where nature and science have combined to regulate and approximate dosage and treatment best suited to produce rapid elimination, improved organic function, and tonic influences. It has been estimated that from this country alone there is annually expended by those seeking health at the radioactive shrines of Europe between $80,000,000 and $90,000,000. This economic feature has served to direct the attention of the medical profession more acutely to the conditions in this country as far as public health is concerned. So common have become those diseases of the heart and arteries due to degenerative changes largely traced to faulty actions of the organs of elimination or from infection from disordered digestive ferments, rheumatism, etc., as to constitute a national menace. It is a well known fact that the vast majority of all of the cases of arteriosclerosis, cardiac affections, and kidney disease should be classed as preventable, and yet recently the Health Commissioner of New York City, Dr. S. S. Goldwater, notes the fact that the "death rate from diseases of the heart and kidneys has approximately doubled in the past thirty years."

During the past few months a society of national scope, the Life Extension Institute, has been organized to direct the attention of the public to a great loss of life daily sacrificed to diseases preventable or curable. (This society estimates 2,500 deaths per day in this class.) "The human clock usually 'breaks down' instead of 'running down,'" states Dr. Eugene Lyman Fisk, and as an example he quotes that " in the United States there were in 1910 more than 100,000 deaths between the ages of forty and sixty, from diseases of the heart, circulation, and kidneys." With then a clear conception as to the importance of this situation, let us consider for a moment just what diseases receive benefit by treatment at the noted spas and clinic centers of Europe, especially those where the radioactive emanation treatments are given, and make deductions as to similar methods of study and treatment that should be applied here.

Emanation therapy applies probably with greatest force and importance in those diseases of the heart, arteries, and kidneys which evidence degenerative changes. In arteriosclerosis and cases of high blood pressure of cardionephric origin, idiopathic in type, emanation is most successful. Various forms of arthritis and muscular rheumatism are promptly relieved. Stubborn neuralgia, myalgia, and neuritis are markedly influenced. Frequently the administration of emanation produces startling results as regards the ferments which control digestion and in the stimulation of general metabolism. Possibly no other known agent can so thoroughly banish the rheumatoid and gout pain. Klemperer states, "Before experience, I expressed myself as very skeptical of the reported success of others, but now I can say that radium scores such success as does no other therapeutic measure in rheumatism."

The immediate change in the blood picture following emanation treatment directs our attention to its use in all forms of anemia and the debilitated states noted in the convalescence from fevers, operations, etc.

Most happy are the results forthcoming in many of the characteristic changes that present themselves with advancing years. That emanation exerts its efforts to sustain vitality at this period is well known, yet possibly over-heralded by those who have perchance witnessed some remarkable evidence of rejuvenation. In diabetic states, as an adjunct remedy it does noteworthy service, due to its influence on the ferments. Early cases most frequently give favorable results. Many of the unpleasant symptoms of diabetes such as pruritus yield promptly.

In nervous diseases emanation produces good effects; even functional disorders show marked improvement. Spinal cord affections respond. The pain of tabes is almost always controlled. Emanation exerts a pronounced sedative and lymphatic action. Time will not permit further reference to the many other conditions, dependent upon faulty metabolism and elimination, that should be listed under therapeutic indications for the use of emanation. The more I study the body of chemistry and electrical phenomena the more disposed I feel toward predicting that many of its processes may be dependent to a considerable degree on radioactivity.

I feel that it will interest you to consider a comparison of the possibilities of treatment at Saratoga as planned under the competent management of the New York State Commission with a few of those famous springs of the Old World. As regards radioactivity, Joachimsthal gives us 185 Mache units of emanation per liter of water; Gastein, 155; Carlsbad, 38; Landeck, 98; Nauheim, 28; Baden Baden, 82. The radioactive content of Saratoga's waters, those for instance of Crystal Rock Spring, according to the measurements of Richard B. Moore and C. F. Wittemore of the Bureau of Mines, Washington, D. C. (subject to some deviation), is 2.4 Mache units per liter of water. While such grouping brings out the fact that the radioactive element of Saratoga's best water presents apparently an insignificant emanation concentration, I am not justified in depreciating its therapy. I append herewith further findings of Messrs. Moore and Wittemore in tabulated form correctly expressed which may be of interest as a matter of record. Crystal Rock in common with many of the other springs shows a small proportion of its activity due to the soluble salts of radium. This feature, however, represents but about 1 per cent. of its total activity.

Although I have no authority to assume that the small activity constant in these springs possesses real virtue, I feel that we should refrain from passing judgment until we are fully aware just how infinitely small radium can be subdivided into dosage and still express physiological activity. Let us take genuine comfort in the fact that Kissingen gives us Rakoczy with 2.85 Mache units; Wiesbaden shows Spiegelquelle and Kochbrunnen Springs with 0.8 Mache units and 1.23 Mache units, respectively; Ferdinandsbrunnen and Ambrosiusquelle Springs of Marienbad give us an activity on only 0.66 Mache units and 1.62 Mache units. These resorts are all credited as being clinically effective. Time and a still better understanding may yet discredit them or it may establish a real merit.

Saratoga has the advantage over most of the foreign springs in having a tremendous quantity of the waters, apparently inexhaustible in their character. Let us be guarded in all statements that lay stress on Saratoga's radioactivity.

A glance across the waters shows us that the favorite method of application at the celebrated foreign "cure resorts" is by use of the bath and "drink cure." Patients for treatment are most carefully examined, every spa being equipped with perfect laboratory facilities. When diagnosis is complete treatments consisting of the proper initial bath and drink dosage are prescribed; followed up by suitable changes in the system, increasing or varying the character of the dosage, as laboratory and clinical findings may indicate.

An emanation bath consists usually of about 200 liters of water and should give an emanation content of not less than 25,000 Mache units. In that it is conceded that very little absorption takes place through the skin, practically, we must count on inhalation of emanation only. The tub should be narrow and high, equipped with a rubber canopy to catch the emanation. A compressed air bubbling outfit is sometimes used to aid in driving emanation from the waters.

Radioactive spring waters for drinking at the spa are administered daily in quantities, divided into three or four doses. Emanation from drinking waters is quickly absorbed, traverses the portal system and to the lungs, there to be all exhaled in about two hours; the larger part of it is probably gone in the first fifteen minutes.

Although large doses of emanation water are gaining in favor, as is indicated in the dosage advocated by the London Radium Institute, which is using from 50,000 to 1,000,000 Mache units, I have seen very excellent reports which represent the results of doses as small as 500 Mache units of emanation. At this point we must express our opinion that a very generous amount of the good results forthcoming at the "water cures" are dependent upon the general character of the waters, plus diet, exercise, massage, etc., tempered with psychic effects much to be desired. Many of the great "cures" abroad have now equipped their institutions with emanatoriums of generous proportions, where the gases from the waters, captured from deep caverns, are taken direct from emanation apparatus generating daily a given amount of the emanation. Many authorities claim the best clinical results are derived from this form of application. When the gas is inhaled it is immediately absorbed by the lungs, which in turn charge the arterial circulation and thus radium traverses every capillary in the body. Where emanation chambers are to be incorporated they should have a minimum dosage of at least 100 Mache units per liter of air and with a capacity of ten times as much for general treatment. Then there are the radioactive mud baths; compresses containing definite amounts of radium for local application, all efficient to a degree. Such are some of the methods by which radium is commonly used at the spas abroad.

With a proper and continued support from the State, I feel most confident in claiming that Saratoga, with its natural resources, can accomplish what these institutions have done, and more. We shall not attain a full measure of success, however, until every facility for treatment is granted. Equally important will be the fostering of the campaign already started to acquaint the medical profession with a better understanding of hydrotherapy, to impart a more keen knowledge of the body ferments, enzymes, and metabolic changes, and to promote a more liberal attitude toward the peculiar forces evidenced in the physiological manifestations of radioactivity.

Not only are the springs of your community to be made available for every form of treatment, this is assured, but elaborate sanitaria for the housing of your visitors must soon be made ready. It will be necessary that these institutions maintain a staff of physicians thoroughly capable as diagnosticians and clinicians and supported by the best men obtainable for the laboratory work. It will also be found necessary either to equip the reservation itself with a large emanatorium and numerous individual chambers or to have such facilities incorporated in the sanitaria.

In certain advanced cases of polyarthritis, neuritis, and in some forms of arteriosclerosis it may be advisable and indeed necessary to administer radium more liberally by the direct use of the soluble salts of radium, given as drinking water or by intravenous injection. Radium for several years has been given internally and by injection in large doses with absolutely no disturbing symptoms. It is accepted as harmoniously by the blood stream as is sunlight by plant life. The use of the soluble salts of radium intravenously transforms the body into an emanatorium and its results are readily noted in increased elimination and a change in the blood picture. The radium is gradually eliminated from the body and finally disappears entirely, but as long as the substance is present it is producing continuous physiological activity.

I append a summary of a few recent radiumtherapy investigations that are well worth careful attention. The first two groups follow the use of emanation waters mainly. The third with emanation and intravenous injections; the last two groups were the results of mainly the intravenous application of soluble radium salts.

You have been exceedingly generous in allowing me much of your time, in which I have stated little as relates to so great a subject. The State of New York has set the seal of its approval upon the work already started and the eyes of the world will watch what you are to accomplish. The careful and conservative administration of the Commission will insure in due season valuable scientific reports as to the real merit of all means of therapy placed at its disposal. Their findings, therefore, will in no small way contribute toward the defense or disavowal of radiumtherapy. If their work follows in accord with methods that science has already unfolded for the restoration to usefulness of the army of sufferers, Saratoga will before another

decade accept its position as the most famous healing place in North America.

THE EPILEPTIC TYPE OF NERVOUS CONSTITUTION.

A RATIONAL PREMISE FOR THE FUTURE INVESTIGATION OF THE EPILEPTIC.

By RUSSELL G. MacROBERT, M.D.,

NEW YORK.

RESIDENT PHYSICIAN, SECOND DIVISION, NEUROLOGICAL INSTITUTE.

ONE individual in every 400 of our population is an epileptic and we have every reason to believe that no race under the sun escapes. The importance of the subject cannot be overestimated. Epilepsy shares with tuberculosis the distinction of having received during the past decade or two a most unusual amount of study and investigation. Reviewing this past investigation of epilepsy we find the greatest literature centering around the search in brain pathology for an organic basis of this disease. Great time and energy have been spent in this pursuit; diligent has been the search for a pathognomonic lesion. Several have been at times accepted but it is unnecessary for these to be reviewed here as to-day there are no pathognomonic signs of epilepsy. All have been overthrown.

Much work has been done on the toxic theory. The fact that convulsions similar in nature to the major attacks of epilepsy occur in the course of diabetes and nephritis and as a sequel to alcoholic and other poisonings led to the theory that many epileptic attacks were due to poisons in the blood. The products of imperfect digestion or excretion as well as extraneous poisons may cause an epileptic manifestation but are only the exciting factors of single attacks.

In support of a toxic theory it has been reported that blood withdrawn from an epileptic during an attack of convulsions will produce convulsions in some small animals. In the small animals this acts only as a poisonous excitant of convulsions, somnolence, and coma. This poison is most likely a product of the excessive metabolic changes of a convulsive attack, as the severity of its action in rabbits and guinea-pigs depends upon the severity of the epileptic manifestation during which the blood is withdrawn.

The more recent investigations seek a solution in two ways: One is a diligent search for a psychogenic origin; the other, which is concomitant with the decision that epilepsy can scarcely be considered a distinct disease, demands that we speak of the epilepsies. Division is attempted into those of organic brain disease, of gastrointestinal, cardiovascular, glandular, toxic, and other origins. This latter is but classifying obtainable exciting causes of attacks and making to accord with them the various epilepsies.

The present day text-books present "the strangest disease in human history" as the enigma it was 25 centuries ago. Why has this subject so baffled human research? Why are we kept at the same position occupied by investigators centuries ago? Why have we found no cause, cure, or explanation?

These questions are answered by one unassailable fact, which is, that the fundamental premise upon which our investigations have been built is the wrong one. Points all through the literature argue the truth. There is no such disease as epilepsy or the epilepsies. Our study was of convulsive phenomena and loss of consciousness—pathological actions of brain cells whose physiological action we are not even able to comprehend.

We can get no further until we realize that there are no epilepsies and recognize the truth that we are dealing with the peculiarities of a distinct type of nervous system. The manifestations by which we diagnosed epilepsy are the natural resultants of irritation on this type of nervous system and part of its syndrome of response.

The loss of consciousness or the convulsion bears to the epileptic nervous type the same relation that any one of the major manifestations of hysteria, such as an anesthesia or a paralysis, bears to the hysterical nervous type. Hysterical stigmata are but peculiar reactions to irritation of a certain nervous makeup or class of individual. The frequency of the epileptic response must be even greater than the frequency of the hysterical response when we recall that there exists one pronounced epileptic for every 400 of our population, and that epilepsy is common to all races. The epileptic with an occasional convulsion may not be half as pathological as his sister, the hysteric.

That the epileptic is so from his earliest moments seems unquestionable. At present we do not recognize this type until we have the evidence of one of its gross manifestations. The secret is at present successfully concealed, till some irritant, physical or psychical, of sufficient degree provoke the latent

epileptic phenomena. Such excitant usually arrives in early life or during the unsettled developmental period of adolescence. Few epileptics reach 20 years of age without having given some major manifestation as proof of their very definite type of nervous organization. Some few may continue on through life and a severe nervous strain or organic disease be required to awaken these inherent peculiarities of action.

The same serious brain disease will not cause epileptic manifestations in all men. In some the phenomena are early acquired and in others the general features of major epileptic response never appear.

The literature abounds with evidence in support of this view. "The excitation is no more than the spark which causes a conflagration; rendered possible only by the chemical constitution of the materials ignited," is a quotation from Gowers' early writings, which seems to be voicing the view presented in this paper. Again speaking of a cause for the first fit he says "When such a cause can be discovered it is usually manifestly inadequate to produce a convulsion by itself and can only be effective in consequence of a powerful predisposition."

Favoring the view that epileptic manifestations are the expressions of inherent properties peculiar to a distinct type of nervous organization and not the result of pathognomonic lesions of any nervous organization are the following lines from the same author: "The various changes that have been described and have been supposed to be related to the origin of this disease have probably no connection with it and do not even deserve enumeration, nor is there at present much likelihood that our knowledge will be more definite. The changes in the nerve centers are probably of that fine kind which is revealed only by altered function and elude the most minute search."

In support of the view that the syndrome of nervous responses expressive of the epileptic type are inherent qualities developed before birth is the unqualified statement by Gowers as early as 1888 that "epilepsy is an inherited disease," and another that "there are few diseases in the production of which inheritance has a more marked influence and the traceable influence is always far less than that which really exists." Voisin, Féré, Nothnagel, Dana, Peterson, Starr, Church, and others express similar views.

Spratling's studies discovered "heredity the supreme agency to which the disease could possibly be ascribed." As to how far heredity is really responsible he says, "A safe reply would be that if such influence had not been present in all probability there would have been no epilepsy."

Church and Peterson say, "It must be admitted that at present the most careful search fails in many cases to detect any histological change known to be morbid."

Spratling in speaking of the organic brain conditions says "such gross lesions do not of themselves cause epilepsy; they are only effective in coexistence with an unstable nervous organization, one predisposed to convulsive manifestations."

These statements are but a few of the many with which the literature on the subject is redundant, that convince us that the fundament of epileptic expressions is an inherent and peculiar principle of one kind of nervous organization.

Each repetition facilitates the onset of the next convulsive outburst. The convulsive habit is recognized as an example of practised nerve action. It, like any other habit, is one of the natural expressions of the nervous system of which it forms a part.

The future research of the epileptic will be in the light of this view. It will be an investigation of the factors that play a part in the prenatal production of a nervous type. The observation of the patient will not be of more use in the future study than a thorough consideration of his antecedents and prenatal influences.

Our now occasionally demonstrated cause we shall view only as the inciting irritant that first revealed the presence of this type of nervous organization. The inciting factors point out to us only what we are not yet able to determine beforehand. At present the epileptic is not often suspected till the appearance of a first convulsion or loss of consciousness.

The secret once disclosed to us, it has been possible in a certain percentage of cases to safeguard our patient from further provocation to gross manifestations. The nervous system is a great child of habit and we must in future strive for an exact description of this nervous type and recognize the epileptic before he has been introduced to the pernicious convulsive habit to which he is by his specific constitution predisposed.

We hope to combat the inherited tendencies by a more definite form of prophylaxis to which our future studies will give rise. Previously we were investigating epilepsy as a disease entity which we were not able satisfactorily to define. We found ourselves involved mostly in a consideration of convulsive phenomena and loss of consciousness, pathological processes of brain cells whose physiological processes we were unable to explore.

Our future investigation will seek to discover influences productive of a definite type of nervous system. The epileptic type of nervous system is one characterized by the peculiar response to irritation on certain occasions, by paroxysms abrupt in onset, variable in duration, usually short, in which there is a loss of consciousness together with a loss of motor co-ordination, usually with convulsions.

Our investigation in future must consider the physical and psychic states of the parents at the time of conception and the environment and psychic states of the mother during the intrauterine life of the child, as well as the earlier hereditary influences and family predispositions. Banishing epilepsy as a disease entity and bringing forward a definite nervous constitution to consider opens a wide range of possibilities. With attention turned to the recognition of the characteristic preconvulsive expressions of this nervous type and more light on the path leading to its causative influences, we may soon be equipped with a more specific prophylaxis.

Our present method of treatment, which is a suppression of the activity of the cells producing the epileptic manifestations, a removal of discoverable irritations, and a combination of these two, will probably give way to a method which will be a better direction of cellular activity.

The idea of epilepsy as a disease entity or a series of diseases should not longer be entertained. We must look upon the epileptic constitution as a type of nervous system that responds in its peculiar manner to any irritation of sufficient degree whether such irritation be a gross brain lesion, a

glandular dystrophy, a gastrointestinal anomaly or toxemia, cardiovascular disease, or the most potent of all, some psychic influence. With the epileptic viewed in this light the future research of this subject is given new wings.

Thanks are hereby expressed to Dr. Charles L. Dana and Dr. Frederick Peterson for their encouragement in the presentation of this view of the epileptic.

119 East Sixty-seventh Street.

CEREALS IN MILK MODIFICATION.*

By FRANK BETHEL CROSS, M.D.,

BROOKLYN, NEW YORK.

ATTENDING PHYSICIAN, METHODIST EPISCOPAL HOSPITAL.

The story of cereal diluents is briefly told. In or about 1876 Jacobi first suggested that cereal decoctions be used in the modification of cow's milk for the very young, and, despite lack of support, for many years he continued to warmly advocate their use. In 1895 Heubner, writing in the *Berliner klinische Wochenschrift*, announced his staunch advocacy of the same principle. Since then others have taken the same stand.

Schiffer, Moro, Korowin, and Zweifel had, in the meanwhile, demonstrated that both the saliva and the pancreatic secretion of young infants possessed amylolytic properties. Kerley and his co-workers verified these early findings nine years ago. In October, 1912, Hess published in the *American Journal of the Diseases of Children* the disclosures of the duodenal tube in infants, establishing beyond all shadow of doubt that the duodenal fluid contains an amylase or starch-converting enzyme. In light of this proof, Wentworth's observation that secretin, the hormone necessary to activation of the pancreas, is not present in the epithelial cells of the intestine of the very young, is open properly to review.

The advisability of the administration of cereal diluents appears to revolve about the problem of their digestibility. Granted that it is established that there is an amylolytic ferment present in the intestinal canal of even very young infants, the question of practical value is how effective this enzyme will be in the presence of a considerable quantity of starch. The starch capacity of infants is a variable factor; at best it is not great, so that if cereals are given too freely, there is poor digestion of the starch content with the usual train of first digestive, then nutritional disorders.

Starch is a polysaccharid, slowly hydrolyzed in the body into first dextrin, then maltose, then dextrose, and consequently, in excess, is never digested with ease. If used in moderation it rarely does harm even if imperfectly digested. Tympanites, with accompanying colic, is rare if the total cereals used is not too great.

The protein of cow's milk is one-fifth soluble whey protein and four-fifths insoluble caseinogen, the latter producing casein when acted upon by digestive ferments. Human milk protein is two-thirds whey protein and one-third caseinogen. As it is the insoluble caseinogen that is responsible for the difficulty in protein digestion and as it is present in such an overwhelming per cent. in cow's milk, we find it desirable to favorably influence its coagulation.

As caseinogen modifiers the cereal decoctions are best known, their addition to cow's milk, through the action of insoluble colloid components, resulting in the formation of smaller, finer, softer and more flocculent casein curds. With such curds digestion is simplified and the digestive capacity conserved. Curds in infant stools are composed of fat, soaps, and fatty acids, large curds generally presenting some protein material as a base. Small curds contain little or no protein. The fats of the milk are further emulsified by the starch.

The use of cereals undoubtedly supplies an additional energy to the food mixture, and this is measurable from the caloric standpoint. The cereal diluent of everyday use is barley, and standard barley-water made with one tablespoonful of flour to each pint of water presents a formula of—fats .05, starch 1.63, protein .09. Oatmeal is richer in fats, rice very poor in fats, wheat a well-balanced cereal. Of all the cereals rice is most easily digested, at the same time being equally nutritious. I question if we use it often enough.

All cereals should be thoroughly cooked, never less than one hour, better two or three hours. The effect of dextrinization is never fixed, as starch, dextrin, and maltose are found in varying proportion, depending upon the length of time of the action of the diastase. With the transforming of some of the starch to soluble carbohydrates (dextrin and maltose), the full mechanical action on the caseinogen is diminished. I take it that no action is had if all the starch is converted.

The teaching of most pediatrists is that cereal diluents in any quantity should not be used in any feeding cases before the age of six months. It is true that the assimilation of protein is not increased by their use, but its digestion is rendered easier through their influence on the caseinogen. The determination of nitrogen waste in the bowel has not been accomplished to date; until some further laboratory process is perfected, no light can be thrown definitely on this problem of the utilization of casein.

Barley or granum decoctions are generally the first to be used, forming about 25 to 50 per cent. of the milk mixture. If marasmus is present, boiled starch in larger quantity is used freely. In malt soup the carbohydrates total 13 per cent. and comprise dextrin, maltose, and lactose as well as unchanged starch. In the lesser degrees of malnutrition a cereal diluent adds to the nutritiousness of the milk formula and may be used as early as two or three months. This is generally appreciated by the manufacturers of proprietary infant foods, as most of these are of cereal origin, either with the addition of dried milk, or with the conversion of the starch into dextrin or maltose.

The administration of cereal solutions alone for a long time, say several weeks, has been known to produce certain symptoms of food deprivation. General atony, hypertonia of the muscles of the arms, legs, or spine, or edema of simple hydremic origin have been observed. These symptoms are most alarming, the edema in some of the cases being so extreme as to suggest diffuse nephritis. The instances reported have been in cases not under medical supervision, but receiving the dietary care of some untrained person.

Cereal dilution is not a feeding "method." Of methods there are many. No one is adequate for all situations, no one method is ideal. But all have merit in varying degree and it should be our aim to feed the individual baby according to his individual needs. Whether we are feeding a healthy baby with

*Read before the Brooklyn Pediatric Society, November 25, 1914.

a normal digestion or a malnutritioned young infant with a subnormal digestive ability, makes a very great difference.

In the latter class of cases cereal gruels have an especial field of usefulness, beyond their routine utilization in the artificial feeding of all children six or more months of age.

832 PRESIDENT STREET.

A NEW CURATIVE TREATMENT FOR PNEUMONIA.

BY FRANCIS E. PARK, M.D.,

STONEHAM, MASS.

I HAVE held back this method of treatment for a period of two years, during which time it has been tried out carefully on a large number of cases of various acute infectious diseases, mostly of the respiratory tract, and in no case have I seen any untoward results. The effect in the milder diseases has not been so striking, because of their comparative innocuousness and also because we have many other agents that are capable of influencing them very materially. In pneumonia, on the other hand, we have a deadly disease, that is not easily influenced, and which annually carries off many thousands of victims. The percentage of cures in all the cases I have observed—and when I use the word "cure" I mean it literally, the patient beginning to improve markedly within a very short time of the administration of the remedy, and convalescence being established usually within three days—has so far been 100. I give here case histories of 12 cases of acute lobar pneumonia, all in adults, the age ranging from 19 years to 90 years.

CASE I.—Mrs. C., 86 years of age, had been suffering from an attack of acute bronchitis for several days, when she was suddenly taken with a chill and with pain in the lung. Domestic remedies were employed for a time and I did not see her until the next day. She had at this time a temperature of 103° and pulse hard and wiry of 110. The cough was very tight, and the mucus that she was raising was thick and yellow, very tenacious and mixed with blood. The physical signs were located in the right lower back. They were, dullness, increased vocal fremitus, and numerous rough, loud râles. A diagnosis of acute lobar pneumonia was made. She was given an intravenous injection of 4 c.c. of my solution and the following morning the temperature had dropped to 99°, pulse to 100. Not only had the temperature and pulse come down, but there was a very decided improvement in her whole general condition. The following day the temperature was normal, and she went on to convalescence with no signs of a relapse.

CASE II.—Woman, aged 51, has been under treatment for several years for functional heart trouble, associated with tachicardia. This patient suffered a severe chill, lasting about an hour, on a Thursday evening, employed home remedies on Friday, and sent for me early Saturday morning. I found her with a temperature of 101.6° and a pulse of 144. She complained of intense pain of a stabbing nature on inspiration. Auscultation revealed crepitant râles over the upper right lung. There was a rusty tinge to the sputum. A diagnosis was made of acute lobar pneumonia of upper lobe of right lung. She was given 2 c.c. of the solution, and counterapplication of a stimulating liniment applied over the inflamed area. That evening the temperature was 102°, a little higher than in the morning, but she was feeling very much better. The pain and distressed feeling were gone. Sunday morning the temperature at 11.30 was 101°, pulse 112. Patient was very comfortable and felt like sitting up. Lung was very much clearer and cough easy. A second intravenous injection of 3 c.c. was given, and in the evening the temperature was 100°, pulse 96. Monday morning the temperature was 99.40°, pulse 100; very little cough; no blood in sputum. Increased vocal resonance was gone. The following day the pulse and temperature were normal.

CASE III.—Woman, aged 39, had been feeling run down for some time; went shopping on a Friday, felt bad all Saturday, and had a chill that night; was sick abed Sunday. I saw her Monday morning, when she had a temperature of 104°, pulse 120. In the top of the right lung was dullness with increased vocal resonance, and many râles, crepitant and coarse; severe headache; complained of great pain in the lung on breathing; was raising thick rusty colored sputum. The diagnosis was made of acute lobar pneumonia of the upper lobe of the right lung. I gave her an intravenous injection of 4 c.c. In the evening the temperature was 102°, pulse 100; patient feeling much better. Tuesday morning the temperature was 101°, pulse 100; numerous râles over the whole area; dullness gone. A second intravenous injection of 3 c.c. was given, and in the evening the temperature came down one degree, pulse 108. Next morning the temperature was 100°, pulse 96; in the evening the temperature was 99°, and the next day normal, with the patient sitting up.

CASE IV.—Man, aged 49, previously well, was exposed to cold on Saturday evening; had a severe chill that night; was abed all day Sunday; sent for me Sunday night. I found a man of full habit, face very flushed, coughing and raising tough sticky rusty sputum. He complained of pain in the back on respiration. Auscultation showed a large dull area in bottom of right lung, with increased vocal fremitus and many râles; temperature 103.6°, pulse 120. The diagnosis was acute lobar pneumonia of lower right lung. Counterirritation was made for the pain, and an intravenous injection of 4 c.c. was given. Next morning the temperature was 102°, pulse 96 and soft. Patient looked like a different man. In the evening the temperature was 102°, pulse 100. The bowels were moved with Epsom salts. On Tuesday morning the temperature was 101°, pulse 96; sputum much thinner and more liquid and containing much less blood. A second injection was given Wednesday morning. Both temperature and pulse were now normal.

CASE V.—Man, aged 69, veteran of the Civil War, had been feeling sick for a day, then experienced a severe chill, and sent for the doctor. He had a temperature of 103.4°, pulse 104; severe stabbing pain in base of right lung, with dullness there, and increased vocal fremitus; crepitant râles; was raising a very thick rusty colored sputum; was profoundly sick; diagnosis, acute lobar pneumonia of the base of right lung. Treatment: Counterirritation for pain; intravenous injection of 4 c.c. Following day the temperature had dropped to 100°, and the next day to normal. He was kept quietly in bed two days longer and then allowed to get up.

CASE VI.—Man, 90 years old, had suffered for some years from enlarged prostate and retention of urine. Otherwise had been very well. He had a temperature of 104°, pulse 110; was coughing hard and raising quantities of bloody sputum; stabbing pain on respiration; dullness and increased vocal fremitus over right back. He was so sick that it almost seemed useless to try and do anything. He was given 3 c.c. that night, and the same amount the next day. In three days his temperature and pulse were normal and the lung cleared up. He was slower in convalescing than the others, owing to a bladder infection that followed catheterization, but in two weeks was about again, and now, six months after, goes out to walk every day.

CASE VII.—Man, 19 years of age; saw him two hours after initial chill; a very septic case; patient stupid, like a typhoid, coughing incessantly and raising a large quantity of bloody sputum; numerous crepitant râles over left back; no dullness on percussion; temperature 105°, pulse 130; diagnosis, acute pneumonia of left back. He was given an intravenous injection of 5 c.c. and ice was applied to the chest and head. In four hours the temperature had dropped 3 degrees and he was rational. Six hours later the temperature was 99°. The following morning the temperature and pulse were normal. He raised rusty sputum for several days longer; no further recurrence of infection.

CASE VIII.—Woman, 79 years old, had been up in the night assisting her sick husband and got chilled; several hours later had a severe rigor and sent for help. She had a pain in her right lung; was coughing. Auscultation showed numerous crepitant râles over the right front; temperature 103°, pulse 110; diagnosis, beginning case of acute lobar pneumonia. She was

given an intravenous injection of 4 c.c. When seen in the morning both pulse and temperature were normal, and after staying in bed for two days she was able to get up and go about again.

Case IX.—Man, 62 years old, addicted to alcohol; had been exposed to very cold, inclement weather; had a temperature of 102.6°, pulse 100; dullness and increased vocal fremitus over left upper lung; severe stabbing pain and raising rusty sputum; diagnosis, acute lobar pneumonia. Treatment: intravenous injection of 4 c.c. Inmprovement was prompt, and in three days the temperature had reached normal. The following day it shot up again and a relapse was experienced—the only instance I have seen since using this remedy. He had an injection on each of the successive days, when the whole condition cleared, and he got up. This was an exceptionally bad case. His condition for a long time previous had been very poor, and, furthermore, his alcoholic addiction was against him.

Case X.—Woman, 49, very fat and full blooded, 5 feet four inches in height, weight 210 pounds. This case I have not my notes on. I remember that the initial temperature was 103°, with a rapid pulse. It came down promptly to about 101° and remained about there for four days. She had three intravenous injections, and on the seventh day the temperature dropped to normal. Although she was of a notoriously dangerous type, yet at no time after the first day was she dangerously ill, and she made a very rapid convalescence.

Case XI.—Man, 65, chronic drunkard, had been sick two days when I saw him; had a well developed pneumonia of right lung. He was very sick, coughing badly and raising quantities of bloody sputum; temperature 104°. He was given 4 c.c. and sent to a charitable institution. Two days later his temperature dropped to normal.

Case XII.—Man, 52, a poor laboring man; has a very bad heart, with big mitral leak; had had a chill the day before, and when I saw him he was a desperately sick man. It looked like an absolutely fatal case. His temperature was 105°, pulse 130 and intermittent; great pain; coughing and raising incessantly rusty sputum. Following morning temperature was 100° and pulse 96; in the evening the temperature had risen to 103°. He was given a second injection. Next morning the temperature was 99° and the following morning normal, and he was soon up and about.

Now here is a series of 12 cases taken from a period of two years. There have been as many more that I feel very sure might have developed into pneumonia had they had a little more time, but they were nipped in the bud. These 12 are undoubted cases. In no case during the time that I have been using this method of treatment have I failed to get a perfect result. I feel that enough time has elapsed and experience accumulated to justify the publishing of this remedy in order that it may receive further trial at the hands of others. If it proves the same with them as it has with me, then we have added a weapon to our armamentarium of great value. I prepare my solution as follows: In 2 ounces of chemically pure distilled water I dissolve 15 grains each of sodium salicylate and the soluble phosphate of iron. This solution is sterilized by heat and on cooling there is added 15 minims of a saturated calcium-creosote mixture, the whole then being passed through a small laboratory porcelain filter. The injections are made through the skin, with an all glass syringe, using a 27 gauge needle, into one of the large veins of the forearm. Great care of course is taken with the asepsis and also to be sure that the needle is within the vein. If properly inserted there will be absolutely no pain. If pain is felt, it means that the needle has gone into the muscle instead, and the injection must instantly be stopped and a new trial made. There may be a momentary flushing of the face and occasionally a temporary nausea. The dose varies from 2 to 5 c.c., according to circumstances. The injection must be made very slowly.

Medicolegal Notes.

Statute of Limitations in Malpractice Action.—In an action for malpractice in the performance of an operation for the removal of gallstones, the Pennsylvania Statute of Limitations, providing that actions for personal injury, not resulting in death, must be brought within two years, was pleaded as a defense. It was held that the bar of the statute applied, and that the statute providing that actions upon the case, other than for slander, shall be commenced within six years, has no application thereto. In Griffin vs. Woodhead (Rhode Island), 74 Atl. 417, which arose under a similar statute, providing that "actions for injury to the person shall be commenced and suit brought within two years next after the cause of action shall accrue and not after," the plaintiff averred the employment of a physician to perform an operation for the purpose of reducing a broken hip, and that the physician so unskillfully and negligently conducted the operation as to cause a permanent shortening of the plaintiff's leg. It was there held that the two-year limitation of the statute applied. In the case of Birmingham vs. Chesapeake & Ohio Ry. Co. (Virginia), 37 S. E. 17, which was a malpractice suit brought against a physician for unskillfully treating a dislocation of the hip-joint, it was held that the action, though brought upon an implied contract, is for a tort or wrong resulting in bodily suffering and injury, and is thus limited by the statute (the Virginia statute limiting actions for injuries to the person to one year after the cause of action arises) to one year. It was there held that the gist of the action was the wrongful injury, and that the plaintiff made use of the defendant's contract merely as an incident in the transaction to show how and why the duty of reasonable care and skill, under the circumstances, rested on the defendant. —Henkel vs. Beitsch, 22 Pa. Dist. 895.

Contract for Treatment by Physician Terminated by Death.—A patient signed a contract to pay his physician $5,000 for his treatment of locomotor ataxia in payments of "$500 every three months till paid." The patient died eighteen months after, having paid at that time $2,375. Six hundred and twenty-five dollars was admitted to be due, and objections were made by his representatives to the allowance by the auditing judge of $2,000 in addition. It was held that, had the treatment consisted of an operation or the prescribing of medicine for a definite period during which the testator lived, the physician's performance of his contract would have been complete and the balance remaining unpaid at the testator's death would have been properly payable to him. But his letters to the testator showed that it was in his mind that the treatment would probably continue for three years. The court applied the principle that generally in all contracts for personal services it is an implied condition that the death of either the employer or the employee dissolves the contract. To hold that the physician was entitled to full payment at any date within the two years and six months for which the payments were to be made would be to say that he might have collected his $5,000 if the testator had died twenty-four hours after the making of the contract, an arrangement neither party could have contemplated. Had the physician died before the treatment was complete no recovery could have been had. It was held that the physician was only entitled to a pro rata payment for the period covered between the date of the contract and the date of the testator's death.—Smith's Estate, 22 Pa. Dist. 1007.

Evidence as to Physical Condition after Injury.—In an action for personal injuries, testimony of a physician as to the plaintiff's physical condition after the accident was held admissible against the objections of the defendant that there was no connection between the injury and the plaintiff's condition as found by the physician and that there was no evidence to show the plaintiff's condition before the accident other than her own statements.—Delong vs. Chicago Railways Co., 187 Ill. App. 432.

Practice of Medicine—Title of Statute.—The title of Louisiana Act No. 49 of 1894 recites that it is an act "to regulate the practice of medicine" and to "provide punishment by fine or imprisonment or both." In proceedings for practicing medicine without a license it was held that the defendant's contention that the act is unconstitutional because its title is not broad enough to cover a prosecution for practicing medicine without a license was not well founded.—State v. Nelson, Louisiana Supreme Court, 65 So. 893.

MEDICAL RECORD.

New York, March 6, 1915.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS.

AT the International Conference on Tuberculosis in Berlin two years ago Gustav Baer described a new method of treating quiescent tuberculous cavities in the lungs. This method consists in the direct surgical approach to the diseased area through the chest wall, the incision of the lung over the tuberculous cavity, and the filling of the latter with a paraffin paste containing bismuth. This method is somewhat akin to that proposed several years ago by Beck of Chicago for the treatment of tuberculous sinuses. Later observations made by Baer tend to strengthen his conviction as to the real value in selected cases of the method proposed by him, and in the *Zeitschrift für Tuberkulose*, December, 1914, he sets forth the results of his more recent experience and describes in detail the technique of this new mode of combating chronic tuberculous foci in the lungs.

The essential steps in the technique of this method are the following: The operation is performed under local anesthesia. A portion of the second or third rib varying in length from four to eight centimeters is removed, the periosteum being carefully spared from injury. The resection is made directly over the cavity which has been accurately located with the aid of the *x*-rays. The costal pleura in the region about the resected portion of rib is carefully separated from the inner surface of the thorax. Large sterile compresses should be at hand, to be introduced into the newly formed space to protect the lung in its vigorous excursions during the act of coughing. Entrance into the tuberculous cavity is effected by means of the Paquelin cautery. The cavity is then packed with walnut-sized plugs consisting of paraffin of a melting-point of 48° to 50° C., with the addition of carbonate of bismuth, 0.5 gram, and iodochloroxyquinoline (an odorless substitute for iodoform), 0.05 gram to every 100 grams of paraffin. These plugs are molded into the cavity without undue pressure being used. The cavity is thus filled up to the stumps of the overlying rib, and the musculature is sutured in one or two layers.

The above operation is followed neither by respiratory nor by circulatory difficulties. The good effects are said to be sooner or later manifested in the diminution in the cough and expectoration and an improvement in the general condition of the patient. Occasionally unfavorable results of the operation are to be observed. The development of emphysema and the presence of hemoptysis suggest that the cavity has broken into the surrounding parts of the lung. Pleural complications are less serious.

The indications for Baer's operation are the presence of local tuberculous foci which have already shown a tendency to heal and which constitute the main lesion in the lungs. The general condition of the patient should be a relatively good one. While slightly less widely applicable than the operation of artificial pneumothorax, the procedure of paraffin plugging is said to be superior in its rapid effects. Moreover, it is regarded as free from many of the disadvantages accompanying the other plastic operations for pulmonary tuberculosis.

SECONDARY INFECTIONS IN HOSPITAL WARDS.

A SUBJECT of considerable interest and importance in clinical medicine is that of so-called secondary infections, the significance of which is most keenly realized in public isolation hospitals in which patients suffering from the same communicable disease are usually treated in the same ward, irrespective of the severity of the disease or of any complications that may be present. This is the common practice in spite of the fact which is well known that a large percentage of the patients admitted to the common ward develop complicating infections which they transmit to one another. To diminish the liability to this transmission strict bed isolation is necessary. However, in spite of all precautions observed, such as preventing contact between the patients, by the careful disinfection of the nurse's or physician's hands after each patient has been attended to, by the placing of screens between the beds, etc., secondary infections arise to an extent much greater than one would anticipate in view of these precautions.

In seeking an explanation for this incidence of supervening or superadded infections two factors must be considered. In the first place the patient himself may harbor, chiefly in his nose and throat, microorganisms which under ordinary circumstances are innocuous but which on account of the weakened resistance of the patient following an infectious disease are able to gain a foothold and give rise to a new infection. In the second place the patient becomes susceptible to bacteria, both virulent and non-virulent, harbored by other patients in the ward, by attendants, or by visitors. To diminish the possibility of antoinfection systematic antiseptic spraying of the patient's mouth, throat, and nose would seem to be called for. To diminish the danger of heteroinfection the admission of visitors to the ward should be restricted, and every effort should be made to prevent contact between the patients and the carrying of droplet infection either directly through the air or indirectly through the medium of the nurse's or physician's hands.

It is impossible in the present state of knowl-

edge to determine what percentage of secondary infections are caused by the patient's own microorganisms, and what percentage are caused by microorganisms transmitted from another. The solution of this problem is, however, not beyond the reach of possibility. If careful bacteriological examination were systematically and repeatedly made of the bodily secretions of every patient admitted to a hospital ward, and if virulence tests were made in the case of every type of organism isolated, one would be able to gain some clue as to the source of supervening infections. But this would not be sufficient. It would be necessary also to compare the results as regards the percentage and nature of secondary infections, by treating two sets of patients under separate conditions: in the one case in the open ward, and in the other case in the cubicle pavilion in which each patient is completely isolated from every other by partitions reaching to the ceiling. Only by means of this comparison may one be able to gauge the extent of secondary infections emanating from the patient himself or from another individual.

The recognized advantages of the block or cubicle system of isolation makes it the ideal method in the management of infectious diseases. The only real disadvantages are the greater expense and the greater inconvenience to which it subjects the nursing and medical personnel of the hospital. When patients suffering from the same contagious disease are treated in the same ward it is necessary to maintain a distance of not less than twelve feet between each bed in order that the possibility of cross infection from one patient to another may be minimized. The security may be increased by the use of glass partitions that do not reach to the ceiling, forming incomplete compartments that seem to serve the purpose in most cases of preventing cross-infection.

HEMORRHAGES IN SCARLET FEVER.

In most of the infectious diseases there is recognized a particularly severe type in which the tendency to hemorrhage is quite marked. One may speak of hemorrhagic measles, hemorrhagic smallpox, etc., which terms are generally synonymous with the malignant types of these diseases. Similarly in very severe cases of scarlet fever hemorrhage may occur into the punctate spots which become petechial. But hemorrhage from the mucous membrane in scarlet fever is an extremely rare occurrence. In fact most of those who have written monographs on this disease scarcely mention hemorrhage as one of the complications. In a careful search of the literature for the past one hundred years W. N. Klimenko (*Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. 3, No. 3) finds that only 89 cases in which this complication was present have been reported. To this total he adds ten cases of his own, occurring among 1,600 cases of scarlet fever that have come under his observation in the course of four years. From the study of all these cases Klimenko reaches a number of important conclusions.

The most common source of the hemorrhage is some part of the arterial system; next in order come the veins; and last, the capillaries. The cause of the bleeding is usually an erosion of the wall of the blood vessel, the result of a suppurative or gangrenous process occurring in the immediate neighborhood of the blood vessel and involving the latter. But there is another important factor that must be considered. In scarlet fever there is a tendency to a degeneration of the muscle coat and elastic fibers of the blood vessels. Most of the hemorrhages in scarlet fever come from the throat; next in order are those from the mouth and nose; then come the hemorrhages from the ears; the fourth site of the bleeding is the stomach; and lastly may be mentioned instances in which hemorrhage may come from two or more of the above mentioned sources. The hemorrhage has a tendency to recur a number of times and is never seen earlier than the second week of the disease. Death is the usual outcome. The treatment demands both tamponade and ligation when these are feasible. The most important point in the prophylaxis is the timely incision of suppurating lymph nodes, particularly those of the neck, in which region the possibility of erosion of the jugulars or of the carotids must be thought of.

PITUITARY STANDARDIZATION.

The rôle of the internal secretions is growing to be better appreciated day by day, though knowledge of the manner in which they act is, at present, inadequate. Enough, however, is known to warrant the statement that in the future organotherapy will play a very great part in medicine. Thyroid extract has long been known to be valuable in the treatment of disturbances of the normal function of that gland, adrenal extract has an assured place in therapeutics, and the same may be said (with some reservations) concerning the extract of the infundibular or posterior lobe of the pituitary body, notwithstanding the fact that as yet no active principle has been isolated from it. This extract has been demonstrated to exert a decidedly stimulating effect upon uterine muscles and to have its uses in obstetrical practice.

One of the greatest obstacles to progress in therapeutics is that medicinal agents are employed before their properties have been accurately gauged. In the case of the pituitary body not only is it necessary to reach a better knowledge of its physiology, but to standardize any extracts which may be obtained from it. In a paper on "Pituitary Standardization" contributed to the Bulletin of the Hygienic Laboratory of the U. S. Public Health Service for November, 1914, Dr. George B. Roth points out that scarcely is any organic or inorganic substance shown to possess physiological activity, than it is placed upon the market as a therapeutic agent, and too often by the manufacturer from other than altruistic reasons. This is often done before any study has been made as to securing an active and staple product. He further points out that manufacturers are not entirely responsible for this condition, as they are frequently obliged to supply the demand created by the physician even though there is no method of stand-

ardization known. Roth has made a fairly exhaustive investigation into some of the physiological properties, and relative activity of the various preparations of the pituitary body now upon the market and he gives a most interesting and instructive sketch of the history, anatomy, physiology, chemistry, and therapeutic uses of the pituitary body. He concludes that the isolated uterus method, in which the degree of activity of the sample of pituitary extract is determined by the force of the contraction it induces in the uterine muscle of a young virgin guinea pig, has been found to be the most satisfactory one. These contractions are compared with those induced by a 1 to 20,000,000 dilution of beta-iminazolylethylamine hydrochloride which is taken as a standard solution. An arbitrary standard of activity for commercial pituitary extracts, making a 1 to 10,000 dilution of the extract equal in activity to 1 in 20,000,000 dilution of the standard when the isolated uterus of the virgin guinea pig is used, is also suggested.

Indirect Mortality from Tetanus.

The experience of the present war is bringing home the fact that tetanus patients even when the convulsions have been permanently arrested face a heavy risk of death from causes by no means to be classed as necessary complications and sequelæ of the disease. Among them may be mentioned bronchopneumonia, gas bacillus sepsis originating in the wound, ordinary sepsis from the same source, and the lighting up of old lesions like syphilitic nodules in the heart. Complete autopsies in tetanus subjects are evidently impracticable in war cases, but if such were performed our knowledge of contributory causes of death would doubtless be much increased. At a recent discussion on tetanus before the Aertzlicher Verein of Hamburg (*Berliner klinische Wochenschrift*, January 4) Fraenkel took up this side of the subject. He had made seven thorough autopsies on men who died in the course of or after tetanus. In but one of these was death due to the latter alone. In the remainder other affections, like those cited above, were either the sole or contributory causes of death.

News of the Week.

American Ambulance Chauffeurs.—Students in Princeton University have contributed $1,100 to the American Ambulance Hospital in Paris. The money will be used for the purchase of an ambulance for wounded soldiers in France. It is expected Princeton volunteers will be assigned to drive the car at the front. Already fifty-seven American men, twenty-four of whom are from Harvard, have been sent to France to drive ambulances.

Red Cross Unit for Germany.—Dr. G. L. Bailey of Oak Park, Ills., and four nurses have been sent by the Red Cross to Kosel, Germany, the party sailing last Saturday on the *Rotterdam*.

Hospital Staff for France.—The French Hospital of New York sent a medical staff of five surgeons and ten nurses to France on the *Touraine* last Saturday. They will have charge of a hospital at Château de Passy, to be known as the French Hospital of New York in France, with accommodations for 100 wounded. The medical supplies and equipment, costing $25,000, were shipped a week earlier in the *Niagara*. The physicians sailing were Drs. Joseph L. Wheelwright, T. C. Walker, W. G. Braddock, A. O. Jimenis, and John S. Irwin. Dr. P. R. Turnure, who is to be the chief of the medical staff, is already in France.

The Last Straw.—To the many wonderful tales, shocking or humorous, which have emanated from the seat of war may be added the report contained in a cable despatch to *The Sun* that a Prof. Friedenthal of Berlin University has discovered a means of converting straw into food. Wood pulp will probably be the next article of diet proposed, and then the Germans can eat their newspapers after reading them.

Casualties in the French Medical Corps.—During the first five months of the war 93 French Army Surgeons were killed, 260 wounded, and 440 taken prisoners.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer of the committee reports the following contributions for the week ending February 27, 1915:

The Monmouth Medical Club, Monmouth, Ill.	$10.00
The Adams County Medical Society, Quincy, Ill.	42.00
Dr. Charles S. Smith, Uniontown, Pa.	25.00
Dr. Frederick J. Walter, Daytona, Fla.	10.00
Dr. Austin C. Brant, Canton, Ohio.	5.00
Dr. William D. Byrne, Chicago, Ill.	5.00
Dr. Simon Levin, Lake Linden, Mich.	5.00
Dr. Miles F. Porter, Fort Wayne, Ind.	5.00
Dr. J. B. Duncan, Pittsburgh, Pa.	10.00
Dr. J. M. Patton, Vandergrift, Pa.	1.00
Dr. N. B. Williams, Perkasie, Pa.	1.00
Dr. Wilson F. Phillips, Dorchester, Mass.	5.00
Dr. Donald C. Balfour, Rochester, Minn.	25.00
Dr. Austin Flint, Jr., New York, N. Y.	25.00
Dr. Evan T. Steadman, Hoboken, N. J.	10.00
Dr. John B. Nichols, Washington, D. C.	10.00
Dr. Hermann G. Klotz, New York, N. Y.	5.00
Dr. George P. Coopernail, Bedford, N. Y.	5.00
Dr. K. I. Sanes, Pittsburgh, Pa.	25.00
Dr. Herman F. Vickery, Boston, Mass.	25.00
Dr. H. H. Atkinson, Fordyce, Ark.	5.00
Dr. Archibald MacLaren, St. Paul, Minn.	25.00
Dr. Helen C. Puna, Providence, R. I.	5.00
Maricopa County Medical Society, Phoenix, Ariz.	25.00
Dr. J. D. S. Davis, Birmingham, Ala.	5.00
Dr. J. M. Popp, New Castle, Pa.	5.00
Dr. Horace Binney, Boston, Mass.	5.00
Dr. Warren Wilson, Northfield, Minn.	5.00
Dr. Gibbs Biscoe, Pendleton, Ark.	5.00
Dr. Eleanore Boulton, Philadelphia, Pa.	5.00
Dr. O. L. Ferry, Elkins, W. Va.	2.00
Dr. John P. Getter, Belleville, Pa.	2.00
Dr. W. H. Witt, Nashville, Tenn.	5.00
Salt Lake County Medical Society, Salt Lake City, Utah	50.00
New York Medical Union, New York, N. Y.	100.00
The Montgomery County Medical Soc., Dayton, Ohio.	304.50
Receipts for week ending Feb. 27.	$807.50
Previously reported receipts.	3,579.00
Total receipts.	4,386.50
Previously reported disbursements.	$3,575.00
Disbursements for week ending Feb. 27, 352 boxes of food at $2.30.	809.60
Total disbursements	4,384 60
Balance	$1.90

The Academy of Medicine Committee for Belgian Relief.—The New York Academy of Medicine has appointed a Committee to receive contributions for a fund for the relief of the Belgian physicians and surgeons, who have suffered as a result of the present war. This Committee is in close touch with those in other places which have the same object in view, and it is convinced that funds contributed can be expended wisely and economically and without duplication and waste.

The Committee believes that this fund should be administered not only to relieve the present suffering, but also to aid in the solution of the serious problems which will have to be faced at the conclusion of the war. It is beyond question that our confrères in that country have undergone, and are still undergoing extreme privation, and that their rehabilitation in practice will be slow and difficult.

Subscriptions to this Fund will be received by

either member of the Committee appointed by the Academy of Medicine. Checks will be deposited in the Astor Trust Company of New York, and the list of subscribers will be published from time to time in the medical journals of New York. The committee consists of Dr. William B. Coley, 40 East Forty-first street, and Dr. William K. Draper, 123 East Thirty-sixth street.

Annual Meeting of the American Medical Association.—In the *Denver News* of February 18, the statement was published that the trustees of the American Medical Association had requested the Colorado State Medical and the Denver County Medical Societies to invite the Association to meet this year in Denver instead of San Francisco, and that such invitation had been extended. Inquiry made at the office of the American Medical Association in Chicago brings the reply that the Association will not change its place of meeting, but will convene in San Francisco, as originally announced.

Gifts to Hospitals.—As a result of the Charity Ball recently given at Philadelphia the sum of $9,200 was realized, and each of the following institutions will accordingly receive $2,300: University Hospital Surgical Ward, Jefferson Hospital Maternity Department, Rush Hospital for Consumptives, Children's Hospital of Philadelphia.

The Robert D. Brigham Hospital for Incurables in Boston benefits to the extent of $50,000 by the will of Mrs. Ellen A. R. Goldthwait. This sum is to constitute a fund to be known as the Joel and Ellen Goldthwait Research Fund, and the income is to be used for work to increase the knowledge of chronic diseases.

By the will the late Mary Rushton, of Philadelphia, residuary bequests are made to the Children's House of the Philadelphia Home for Incurables and the Hospital of the University of Pennsylvania.

The National Committee on Mental Hygiene has recently received a gift of $44,500 from Miss Elizabeth Milbank Anderson and one of $40,000 from Mrs. William K. Vanderbilt, and the Rockefeller Foundation has agreed to contribute the money necessary to retain the services of Dr. Thomas W. Salmon as medical director of the Committee. At a meeting of the National Committee in this city on February 17 the following officers were elected: *President*, Dr. Lewellys F. Barker; *Vice-Presidents*, Dr. Charles W. Eliot and Dr. William H. Welch; *Treasurer*, Otto T. Bannard; *Medical director*, Dr. Thomas W. Salmon; *Secretary*, Clifford W. Beers; *Executive Committee:* Dr. August Hoch, chairman; Dr. George Blumer, Miss Julia C. Lathrop, Dr. William Mabon, Dr. William L. Russell, and Dr. Lewellys F. Barker.

Harvey Society Lectures.—The final lecture of the course will be delivered at the New York Academy of Medicine on Saturday March 13, at 8:30 P. M., by Prof. Elliott P. Joslin of Harvard University. The subject of the lecture will be: "Carbohydrate Utilization in Diabetes, Based upon Studies of the Respiration, Urine, and Blood."

In Support of the State Health Department.—The New York State Conference of Mayors and Other City Officials, through its legislative committee, is urging adequate appropriation for the State Department of Health on the ground that the educational campaign of that department strengthens the work of local departments and gives it a backing without which local departments would be unable efficiently to carry on such work. The resolution adopted by the committee cites the fact that the first Conference of Mayors devoted its entire program to "The City Healthful" and became thereby a pioneer in the agitation which brought about the demands for the present excellent State health law.

New Division of Industrial Hygiene.—The New York City Department of Health is about to establish a Division of Industrial Hygiene, which will be under the general supervision of the Director of the Bureau of Infectious Diseases, and which will be closely associated with the Bureau of Public Health Education.

Change in the Period of Quarantine in Cases of Scarlet Fever.—In accordance with the effort now being made to bring the public health regulations and laws in this city into conformity with those of the State Department of Health, the quarantine period in cases of scarlet fever occurring in New York City has been fixed at "thirty days and until discharges have ceased and the disinfection of the person has been carried out," instead of the thirty-five day period of quarantine previously enforced in this city.

Death Rate in New York.—For the week ending February 20, the death rate in this city was 14.11 per thousand of population as compared with 16.52 for the corresponding week of 1914. The rate since January 1 has been 13.95 as compared with 14.85 during the corresponding period last year.

Dogs Must Be Muzzled.—The validity of the Board of Health order requiring that all dogs be muzzled has been upheld by Supreme Court Justice Lehman. In his decision the judge said: "In spite of the discussion as to the prevalence or even the existence of this disease (rabies) the prevailing opinion, both lay and medical, is that such a disease does exist and is a menace to public health. * * * The disease can become completely eradicated if it becomes impossible for one rabid animal to bite another animal or human being, and the disease can be controlled in exact proportion that control and protection from such bites can be secured."

Dr. J. M. Godfrey, Past President of the General Council of the Alpha Sigma Medical Fraternity, was the recipient of a silver service at the hands of his fraternity brothers at the annual dinner held at Philadelphia on February 22.

Medical Society Elections.—The Waterbury (Conn.) Medical Association, at the annual meeting held January 11, elected the following officers: *President*, Dr. John E. Farrell; *Vice-President*, Dr. Myron L. Cooley; *Secretary*, Dr. Egbert L. Smith; *Treasurer*, Dr. Charles E. Rodman; *Executive Committee*, Drs. Farrell, Rodman, and Dudley B. Deming; *Literary Committee*, Drs. Cooley, Smith, and Carl E. Munger.

The Santa Clara County (Cal.) Medical Association at a regular meeting held in San José on December 16, elected the following officers: *President*, Dr. Charles M. Richards; *Vice-Presidents*, Drs. James Blair, T. M. Williams, and John Clarke; *Secretary*, Dr. Charles B. Hare; *Treasurer*, Dr. H. B. Wright; *Counselors*, Drs. N. H. Bullock, Frank H. Patterson, and S. B. Van Dalsem; *Delegates to State Society*, Drs. N. H. Bullock and J. A. Bacher; *Alternates*, Drs. M. W. Kapp, Paul Sanford, and P. A. Jordan.

The Pottsville (Pa.) Medical Club, at a meeting held January 7, elected the following officers: *President*, William F. Doyle; *First Vice-President*, Dr. A. L. Gillars; *Second Vice-President*, Dr. John

Striegel; *Secretary-Treasurer*, Dr. John J. Moore; *Board of Membership*, Drs. G. R. S. Corson, J. L. Warne, and C. D. Miller.

The Nashville Academy of Medicine and Davidson County (Tenn.) Medical Society, at a meeting held January 5, elected the following officers: *President*, Dr. W. E. Hibbert; *Vice-President*, Dr. H. M. Tigert; *Secretary*, Dr. J. F. Gallagher; *Delegates to the State Association*, Drs. McCabe, Tigert, and Caldwell.

The Fayette County (Pa.) Medical Society, at the annual meeting held in Uniontown January 7, elected the following officers: *President*, Dr. A. E. Crow; *First Vice-President*, Dr. J. Holmes Sangston, of McClellandtown; *Second Vice-President*, Dr. E. C. Sherrick, of Connellsville; *Secretary*, Dr. Joseph P. Ritenour, of Uniontown; *Treasurer*, Dr. J. E. Van Gilder, of Uniontown; *Reporter*, Dr. G. H. Robinson, of Uniontown; *Censors*, Drs. O. R. Altman, of Uniontown; T. B. Echard, of Connellsville, and H. J. Bell, of Dawson.

The Muscatine (Iowa) Medical Society, at a meeting held December 29, elected the following officers: *President*, Dr. A. J. Weaver, Muscatine; *First Vice-President*, Dr. F. L. Appell, Muscatine; *Second Vice-President*, Dr. W. A. Cooling, Wilton; *Secretary-Treasurer*, Dr. R. M. Arey, Muscatine.

The Kennebeck County (Maine) Medical Association held its annual meeting in Augusta on January 1, electing the following officers: *President*, Dr. Ralph D. Simons, of Gardiner; *Vice-President*, Dr. H. K. Stinson, of the National Soldiers' Home at Togus; *Secretary*, Dr. S. J. Beach, of Augusta; *Treasurer*, Dr. G. R. Campbell, of Augusta; *Censors*, Drs. B. D. Ridlon, of the National Soldiers' Home at Togus; A. B. Libby, of Gardiner; L. G. Bunker, of Waterville; *Delegates to the Maine Medical Association*, Drs. T. E. Hardy, of Waterville; D. B. Cragin, of Waterville, and S. J. Beach, of Augusta.

The Langlade County (Wis.) Medical Society, at the annual meeting held at Antigo on December 23, elected the following officers: *President*, Dr. F. V. Watson; *Vice-President*, Dr. H. G. Westphal; *Secretary-Treasurer*, Dr. J. C. Wright; *Censor*, Dr. M. J. Donohue.

Obituary Notes.—Dr. Homer Gibney of New York died suddenly on February 16, aged 55 years. He was a graduate of the Atlanta Medical College, Atlanta, Ga., in 1893, assistant surgeon to the Hospital for the Ruptured and Crippled, Out-Patient Department, consulting orthopedic surgeon to the Italian Hospital, the Somerville Hospital, and the Rockaway Hospital, orthopedic surgeon to the West Side German Dispensary, and a member of the New York Academy of Medicine and the Society of the Alumni of the Roosevelt Hospital.

Dr. John Wesley Gray of Bloomfield, Ind., a graduate of the Jefferson Medical College, Philadelphia, in 1864, and of the Bellevue Hospital Medical College, New York, in 1867, died at his home, after a short illness, on January 25, aged 75 years.

Dr. Harry Clifton Boutelle of Danvers, Mass., a graduate of the Harvard University Medical School, Boston, in 1899, a member of the Board of Health of Danvers, and of the American Medical Association, the Massachusetts Medical Society, and the Essex District Medical Society, died at his home from pneumonia, on January 25, aged 39 years.

Dr. Samuel W. Langmaid of Boston, Mass., a graduate of the Harvard University Medical School in 1864, consulting laryngologist to the Massachusetts General Hospital, and a member of the American Medical Association, the Massachusetts Medical Society, the Norfolk District Medical Society, the American Laryngological Association, and the New England Otological and Laryngological Society, died at his home in Brookline, on February 3, aged 77 years.

Dr. Thomas Carney of Schenectady, N. Y., a graduate of the Albany Medical College, Albany, N. Y., in 1902, a major in the National Guard of the State of New York, and a member of the New York State and Schenectady County Medical Societies, died at the Johns Hopkins Hospital, Baltimore, on February 6, following an operation for gastric disease.

Dr. William G. Schmidt of Quincy, Ill., a graduate of the Missouri Medical College, St. Louis, in 1891, and a member of the Illinois State and Adams County Medical Societies, died at his home on January 16, aged 54 years.

Dr. Isaac Shelby Warren of Somerset, Ky., a graduate of the Kentucky School of Medicine, Louisville, in 1871, and a member of the Kentucky State Medical Association and the Pulaski County Medical Society, died at the Somerset Hospital, following an operation for cancer, on January 15, aged 59 years.

Obituary.

JAMES FRANCIS DONNELLY, M.D.,

NEW YORK.

On the roll of Red Cross martyrs must be inscribed the name of Dr. James F. Donnelly, who died at Gevelegi, near Nish in Servia, on February 24. He was born in Boston, July 15, 1874, and was graduated in medicine from the University of Louisville. He had had an adventurous career, having seen active service in South Africa during the Boer war and later on the West Coast of Africa. For a number of years he was surgeon on the boats of the Holland-America Line, was for a time in Dalny, and then accompanied, in the capacity of medical officer, an expedition to the head waters of the Amazon in Peru. He was for nearly a year in Hayti, working to improve the sanitary condition of some of the ports in that country, and later was boarding officer at the New York quarantine station. He left New York last November in company with five other physicians and twelve nurses sent by the American Red Cross. When volunteers were called for to take charge of the pest hospital at Gevelegi Dr. Donnelly offered his services and while there contracted typhus fever, which caused his death.

Correspondence.

MEDICAL NEWS IN THE "NEW YORK TIMES."

A DENIAL FROM THE GENERAL MEMORIAL HOSPITAL.

To the Editor of the Medical Record:

Sir:—On Friday, Feb. 19, the *New York Times* featured an article on a "New Cancer Serum," said to have been devised at the General Memorial Hospital and used with curative effect on hopeless cases in the last stages of the disease. So much technical detail was interwoven in the statement as to make it appear that the report had been derived from an authoritative source and such extravagant claims were credited to the Medical Board as gravely to impugn their scientific judgment if not their per-

sonal veracity. Although prompt denial of the authenticity of the article was made by a member of the Board of Managers of the Hospital and published in the *Times* on the following day, the Medical Board of the Hospital feels that a more detailed reply is owing to the medical profession, and to such portion of the public as is within their reach.

While it is impossible to discuss in detail every error in the report, it is possible to deny categorically the chief assertions made in the article, which we wish to do as follows:

1. "The therapeutic agent is a serum of a kind never before used." We are not at present using at the Memorial Hospital any serum whatever.

2. "It is the opinion of those watching the effects of the new serum that it has already superseded the use of radium and *x*-rays." No such opinion is held by any member of the Board regarding any treatment ever employed at this hospital. On the contrary, very elaborate equipment with both these physical agents is constantly being employed at the hospital to the limit of capacity and we see no indication that the demand for radium and the *x*-ray is likely to diminish.

3. The article imputes to us the belief that recurrences after disappearance of cancer under radium treatment are frequent and sometimes more malignant than the original disease. We disclaim any responsibility whatever for this opinion and are not prepared to express judgment on the ultimate effects of radium.

4. "Patients afflicted with cancer of the breast and involving the adjacent smaller glands have been successfully treated by the serum." The only encouraging results we have had with this group of inoperable cases have been with the *x*-ray and here our observations agree with those of radiologists generally.

5. The reference to two specific cases of epithelioma of the temple and cancer of the tongue, said to have been cured by this serum, do not correspond with any observations made in this hospital. There have been no such cases in the institution.

6. "They forecast this report as one of the most important contributions to science emanating from the medical profession of the country." We decline to accept responsibility for any such promise. We have no such report in contemplation. We know of nothing that seems likely to prove a constitutional remedy for advanced cancer. All we hope to do at the General Memorial Hospital is in the line of painstaking study of different forms of cancer, the persistent application of well attested remedies and palliatives in the disease, and the investigation of such other methods as present a sound theoretical basis, always with strict regard to the interests of the individual patient.

7. Finally we desire to state that the article in the *New York Times* was published against the energetic protest of the only member of the Board who was interviewed in regard to it.

In an editorial comment on February 22 the *Times* states: "Real newspapers will continue to exercise their own judgment as to what they will or will not print. That is their business and some of them perform it perhaps with a sense of responsibility, as deep as is that of the most ethical member of the profession." Nevertheless we submit that as a result of publishing the statement, in question, the work of the hospital has been seriously interfered with, the time of its staff has been wasted, the seeds of misunderstanding and mistrust have been sown, the good name of honest investigators in a difficult field has been jeopardized, and false hopes have again been roused in the minds of unfortunate sufferers all over the country.

For the Medical Board, General Memorial Hospital,

JAMES EWING,
W. B. COLEY,
RICHARD WEIL,
S. P. BEEBE.

PROSTATIC ATROPHY AND MUMPS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The close, one is tempted to say mystical, connection between the parotid gland and the testes is well known. That an attack of parotitis may result in atrophy of the testes, in aspermia or azoospermia with complete sterility, is also well known. Hardly known, however, is the connection between the parotid and the prostate, and still less known is the fact that an attack of parotitis may cause atrophy of the prostate without apparent involvement of the testicles and the spermatogenetic function. The sterility may, however, be just as absolute nevertheless, for a normal prostatic secretion is an important constituent of normal seminal fluid and its absence seems in many instances to be alone responsible for the lack of fertilizing power of the latter.

The writer has had seven cases of partial or *complete* (so complete that not a vestige of prostatic tissue could be made out) atrophy of the prostate, in which an antecedent parotitis seemed to be the sole etiological factor; in some of these cases (five) the atrophy was accompanied by atrophy of the testicles; in two the testicles seemed to be unaffected. These interesting cases will be reported in detail later on. But the object of these lines is to call the attention of the profession to the connection between the parotid and the prostate, and to ask them to report, either in the pages of the MEDICAL RECORD or to me directly, any cases of prostatic atrophy in which parotitis was the positive or probable etiological factor.

The relationship existing between far distant glands, organs, and tissues and the genital organs forms a fascinating field of study and research.

WILLIAM J. ROBINSON, M.D.

12 MT. MORRIS PARK W.,
NEW YORK CITY.

THE ATLANTIC COUNTY MEDICAL LIBRARY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of February 20, in the list of Medical Libraries, you fail to mention the Library at Atlantic City. This is situated in the building of the Atlantic City Public Library but is under the direction of the Atlantic County Medical Society. It contains about 1500 volumes. It is our desire that the physicians who come to Atlantic City may know that our library is at their disposal at all times, and I would thank you to give this publicity to its existence.

W. EDGAR DARNALL, M.D.

ATLANTIC CITY, N. J.

The Suprarenals in Shock. — G. Romano concludes from his experiments on dogs that in the condition of shock there are dynamic and functional changes in the suprarenals, consisting in a marked reduction in the adrenalinogenic power of the medullary substance.—*Riforma Medica.*

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PARLIAMENTARY DISCUSSION ON ANTITYPHOID INOCULATION—CRIMINAL ABORTION—ROYAL MEDICAL BENEVOLENT FUND—RED CROSS AND AMBULANCE REPORT—MILITARY SERVICE AND HEALTH.

LONDON, February 12, 1915.

THE antis have managed to make a raid in the House of Commons on two days this week, but they have sustained so decisive a defeat that they might well bury their prejudices. This resulted from the union of the two parties, for the opposition joined the government forces on this question. The question arose on the vote for the army, when Mr. Peto expressed surprise that any one should oppose inoculation against typhoid so strongly favored by every great medical leader. Typhoid, he said, had practically disappeared among our troops in India, and in the present war the preventive against death was absolute. In the Boer war there were more deaths from typhoid than from the enemy. In the United States army inoculation was compulsory. Then Mr. Chancellor spoke for the antis, complaining that they were boycotted by the press and declaring that although ministers assured men they were not compelled to be inoculated, officers exercised so much influence that it often amounted to terrorism. He told a tale from a letter he received this year about a young man, the only one in his company of "a good many," who declined to be inoculated, and was called a fool and a "dirty dog" by the medical officer, with other opprobrious terms emphasized with profanity. It is certainly disgusting to think a qualified man should disgrace the profession which claims to consist for the most part of gentlemen, but the insulted young man appealed to a superior officer with the result that an apology was tendered. Mr. Chancellor said he did not object to proper persuasion, but to methods amounting to coercion and to the falsehood that opponents of inoculation were deterring recruiting. Sir H. Craik protested against the attack on the honor of the profession whose united opinion was surely preferable to Mr. Chancellor's *ipse dixit*. Then Dr. Addison, who is parliamentary secretary to the Board of Education, put in the defense of the government in an admirable speech in which he pointed out that in the present campaign only 421 cases of typhoid had so far occurred, against 58,000 in the South African war. It was not contended that an inoculated man could not suffer from typhoid, for in fact cases had occurred, but they were so few and the protection was so great that the plan was worth trying. He admitted it was wrong to press the consciences of men, as stated by Mr. Chancellor, whose condemnation should, however, extend to the agitation carried on by his own party by leaflets, manifestos, and people going about the camps urging opposition to inoculation. He understood a possible excess of zeal in an officer taking out a company who felt the burden would be less with fewer sick, and so more units on the firing line. Then Mr. Long, as leader of the opposition, announced that his party would give their support to the government, and hoped they would not by weakness or vacillation add to the decimation of our forces owing to a cause which they could prevent. He believed strongly in inoculation, in vaccination, in vivisection. The pledge given to men enlisted not to compel was binding, but with regard to the future it was for consideration. Mr. Tennant, Under Secretary for War, said evidence for compulsion was accumulating. In India over 90 per cent. were inoculated voluntarily. Previous to compulsion 2,000 cases of typhoid occurred annually. In 1913 there were only 85. Lord Kitchener felt the danger of noninoculated men on leave bringing back typhoid unless they got inoculated. Of our men in France, 34/35ths of the deaths were of the noninoculated. Mr. Chancellor had said zealous officers were conscientious men with a flame burning inside them. But when the flame was about to light the wrong gas it was better to extinguish it.

The Society of Medical Officers of Health has had before it a paper on "Criminal Abortion and Abortifacients," by Dr. W. F. J. Whitley, who said of three ways in which it was attempted the commonest was purgation, the other two being, 1, by drugs having a supposed or real action on the fetus itself or else on the uterine muscle; 2, by mechanical interference. He thought an unsuccessful attempt might perhaps have more serious and far-reaching effects than a successful one, as a maimed, disfigured infant might be born, undeveloped, and possessed of scarcely any power of resistance. Among poisonous drugs, diachylon was much resorted to in the northeast of England, taken in combination with aloes. Some chemists had agreed not to sell it without a doctor's prescription, but there was evidence that it was sold freely by herbalists, many of whom were, in fact, abortionists. Suggested measures for checking the crime were scheduling diachylon as a poison, notification of pregnancy, education as to ante-natal hygiene, notification of all abortions or miscarriages, and a pathological examination of fetus and placenta in every case. Dr. Willoughby admitted that a disastrous effect might follow the ingestion of abortifacients, but feared their use would not be much restricted by scheduling same. The root of the mischief was that a mother was not looked upon with the respect to which she was entitled. People should be warned that drugging might prevent healthy infants being born. Dr. S. C. Lawrence referred to the difficulty of deciding, in presence of an abortion, whether drugs had been taken. Mr. Hichon said in the north of England instruments were more commonly used than was realized. The first preventive step was to stop suggestive advertisements. Dr. Hutt asked what evidence there was of injury to the child after an unsuccessful attempt. If incorrect the statement might do harm. The president, Mr. Herbert Jones, agreed that advertisements of abortionists ought to be stopped. He said the very herbalists who were receiving payments from the State under the insurance offer sold abortifacients. Perhaps your readers will think that the society, instead of confining itself to talk about the evil, might have done better to make a forcible representation of the facts to the government.

Queen Amélie of Portugal took the chair at the annual meeting of the Royal Medical Benevolent Fund Guild, held at the Royal College of Physicians on the 4th inst. The report of the Council urged the need of new branches and more workers. The plan had been one of quiet endeavor and the treasurer pronounced the financial position satisfactory. The war had taken toll of the profession, 73 R. A. M. C.'s having been killed, and on their list were several widows who, besides their poverty, had the anxiety incident to their sons being at the front. The Guild was instrumental in assisting many of these cases and providing for the education and training of other children.

The Red Cross and St. John's Ambulance Societies have made a joint report of their work during the first six months of the war. On its outbreak they received offers of convalescent homes for sailors and soldiers amounting to a provision of 21,339 beds. At present they have 705 auxiliary home hospitals containing 19,576 beds, most of them organized, opened and staffed by voluntary aid detachments under control of the military authorities. About 300 officers have been placed in convalescent homes, 25 sent to Switzerland (some with their wives), traveling and hotel expenses being paid for them. Hospitality has been arranged for a number of Belgian officers and their families. A house with 400 beds given by Messrs. Bourne and Hollingsworth has been handed over to the Belgian Government, and is now King Albert's Hospital. Another house, with 300 beds, has also been given for a convalescent home for Belgian soldiers.

The value of national military service from a physical and medical point of view formed the subject of a lecture by Dr. Leslie at the Institute of Hygiene. To any mother who asked if her son was strong enough to enlist, he declared the answer always was "Yes," for the profession was well aware that the training meant an almost infallible regeneration of physical and mental power. In a specific instance 350 recruits, drawn more or less from the lower strata, 20 per cent. who seemed scarcely fit for service could, after three months, pass any test. The others, who had originally passed, were immeasurably improved. Young men were beginning to realize the value of feeling fit—a fitness which awakened soul as well as body. In heart cases civilians exceeded by 20 per cent. the number of army men.

The progress of the Japanese in physique and intellect since the introduction of national service was almost magical. The same was true of the Australian commonwealth. The British army had more cases of heart disease than the French, Austrian, and Russian armies put together. Our climate with its creation of rheumatism must, however, be remembered in this connection.

1. The Treatment of Diabetes.—F. M. Allen bases his method of treatment upon the conception that diabetes is the result of a simple weakness of the pancreas without an inherent downward tendency. The first step in the treatment is to have the patient fast till glycosuria ceases, and then for twenty-four or forty-eight hours longer. At the same time, the ketonuria falls steeply. It quickly approximates what a normal individual would show under similar conditions, and the aim is to keep it constantly down to this level. Plain fasting suffices for the purpose; but since alcohol is a food which does not produce glycosuria and is said to diminish ketonuria, it is generally given during fasting, especially if there is danger of coma. Its use or omission in later treatment depends upon individual conditions. Alkalies may be useful for the first few days if coma seems imminent, but are then no longer needed. Continuing the sodium bicarbonate may cause the ferric chloride reaction to remain positive longer than it otherwise would, with no benefit to the patient. When the fasting patient has been free from glycosuria for twenty-four to forty-eight hours, the next step is to begin feeding very slowly and cautiously. There need not be a fixed program. It is desirable to individualize the diet to suit the needs of different patients, and various physicians may have personal preferences of their own. The one requirement is that the patient must remain free from both glycosuria and acidosis. Any trace of sugar is the signal for a fast day, with or without alcohol. The original fast, to clear up the urine in the first place, may be anything from two to ten days, but after that no fast need be longer than one day. The things to be considered in the diet are carbohydrate, protein, fat, and bulk. Frequently the first thing given after the fast is carbohydrate. No distinction is necessary between different forms of starch, but there are advantages in using vegetables, following Joslin's convenient classification on the basis of carbohydrate content. The first day after fasting, the only food may be 200 grams of vegetables of the 5 and 6 per cent. classes. This is increased day by day until a trace of glycosuria appears, which is checked by a fast day. The purpose of such a program is to learn the carbohydrate tolerance and to clear up the last traces of acidosis. After this carbohydrate period, or sometimes in place of it, protein is given. On the first day perhaps one or two eggs are given, and nothing else. More protein, generally as eggs and meat, is added day by day, until the patient either shows glycosuria or reaches a safe protein ration. The purpose here is to learn the protein tolerance, and to cover protein loss as quickly as possible. Fat is somewhat less urgently needed, except in very weak and emaciated patients, and it can be added gradually, as conditions seem to indicate. An element of bulk in the diet is necessary to give the comfortable feeling of fulness, and to prevent constipation. This is the great advantage of green vegetables. When these green vegetables are fed raw, the author says, or cooked in steam, or boiled and evaporated so that none of the water is thrown away, they contain a definite quantity of carbohydrate, besides valuable salts.

3. Tuberculous Mesenteric and Retroperitoneal Glands.—E. H. Risley concludes that tabes mesenterica is often a primary disease with sometimes a fairly distinct clinical history and signs. It most often simulates acute appendicitis, and when in this stage should demand surgical intervention. In the absence of palpable glands, however, it is impossible to make a correct pre-operative diagnosis in many cases, there being no symptom-complex distinctive enough of this condition. A great many people harbor tuberculous mesenteric glands in various stages of activity without symptoms. The disease has two clinical types: a slowly progressing one, generally with palpable glands, and an acute fulminating type, most often simulating and impossible generally to differentiate from appendicitis. The prognosis in the subacute stage is good without operation. In the acute stage exploratory laparotomy should be done, but the glands not removed unless there are definite indications either from adhesions, ulceration, or size of mass producing pain or mechanical obstruction. In children and young adults with a history of right-sided abdominal pain, with or without the presence of palpable masses, tabes mesenterica, the author says, should always be considered as a possibility.

1. Drainage of the Seminal Vesicles.—J. Bentley Squier draws the following conclusions from the study of fifty consecutive operations upon the seminal vesicles. Operative drainage of the vesicles for chronic focal infection has produced in this series a cure in 68 per cent. of all cases operated upon, improvement in 24 per cent., and no improvement in 8 per cent. The largest percentage of cure has been among those cases in which arthritic symptoms predominated: Cured, 76.4 per cent.; improved, 23.6 per cent. The author's experience with drainage of the seminal vesicles in patients suffering from arthropathies seems to indicate that the amount of relief to be expected in any given case will largely depend upon the length of time elapsed between the acute urethral infection, the appearance of the joint lesion, and the operation for drainage. After ankylosis from fibrous or bony changes has taken place, operation upon the vesicles will offer but little except toward arresting further joint destruction. Next in order of operative relief is the pain group, in which cure resulted in 66.6 per cent. of cases, improvement in 25 per cent., and no improvement in 8.4 per cent. The least satisfactory have been the pus group, in which cure resulted in 61.9 per cent., improved in 23.8 per cent., and no improvement in 14.3 per cent. The reason this group has been the least productive of favorable result is obvious. In most instances the infection in the vesicles is only a part of a pan-infection involving prostate, urethra, and bladder neck. This group of cases may be found to require excision of the vesicles and prostate if cure is to be expected in every case. Twenty-five per cent. of the pain group were complicated by calculi of the vesicle. Where neurasthenic symptoms were associated with any of the symptom groups there has been a complete amelioration of these symptoms. Approximately 10 per cent. of the patients suffered from a postoperative impotence. This was transient in all but one case, where it had continued up to the present, and in which there was a preoperative impotence. The other cases in from two to six months regained their sexual capacity in every instance. The majority of patients suffering from chronic seminal vesiculitis had already manifested an impairment of sexual function irrespective of operation. The important corollary is that a surgeon should definitely ascertain the exact status of a patient's sexual function before operation is decided upon, in order to guard against having the operation considered as the cause of an already existing impotence.

2. A New Reaction in Syphilis.—A. Gordon describes this test as follows: One-half cubic centimeter of blood serum is placed in a test tube. Five drops of a one per cent. solution of bichloride of mercury are slowly allowed to fall in the center of the tube. The following phenomenon is observed. If the serum comes from a normal individual or from an individual suffering from other diseases, but free from syphilis (as proved by a Wassermann test), the moment the reagent comes in contact with the serum a cloudiness will appear which will rapidly increase in density so that at the end of five and sometimes ten minutes the entire or almost the entire amount of serum will present a thick gray mass with a slightly greenish tint. In some cases the thickness appears at once, in other cases shortly after the dropping of the reagent, and in still other cases five or ten minutes later. In syphilitic serums the contact of the reagent produces not the foregoing thick mass, but only a foamy upper layer which remains as such for some time. Here one observes a distinct slight upper whitish and foamy layer beneath which the normal serum is evident; the latter preserves the same appearance and color as prior to the manipulation.

5. Etiology of Foot and Mouth Disease.—F. Proescher reports the results of his examination of smears taken from the pustular contents of two cases of foot and mouth disease. The smears which were stained with methylenazur showed an enormous number of extremely small cocci in the form of deplococci or diplobacilli sometimes appearing in short chains and closely packed together. The majority of the microorganisms are just within the limit of microscopic visibility (0.1 micron); the largest form are about 0.2 of a micron. They are metachromatic violet blue; few are stained deep blue. In places where the organisms appear widely separated they seem to be surrounded by a small colorless capsule. These microorganisms are the smallest of the visible filterable viruses, being smaller than either poliomyelitis or rabies microorganisms.

11. Roundworm Within the Body of a Tonsil. A. B. Middleton.

3. Gastric Cancer.—F. Smithies states that there is at present no known medical cure for gastric cancer. There is, as yet, no dependable means at one's command for the recognition of the disease at a stage when one can positively state that the affection is surgically curable. The cases of gastric cancer early diagnosed are those in which the clinical symptomatology is that which one associates with chronic gastric ulcer, and in which laparotomy has been urged on the suspicion that cancer might be present. Where microscopists disagree regarding the diagnosis of sections of extirpated tissue, clinicians can scarcely be expected to make an early diagnosis of gastric cancer before laparotomy. The question for clinicians and pathologists to settle is not how many cancers had previous ulcer pointings, nor how frequently gastric ulcer changes from a simple to a malignant form, but just how one is to tell, clinically, in a given case of chronic gastric ulcer, what future course it is destined to pursue. This is the crux of the situation. At present there is no means of prognosing the future course of any gastric ulcer, acute or chronic. The life history of the affection seems to depend on certain unknown factors that are apparently highly individual.

5. The Cellular Factor in Infectious Diseases.—D. Riesman suggests a new classification of bacterial infections as follows: (1) The productive infectious diseases, characterized by cellular proliferation. (2) The non-productive infectious diseases, not so characterized. To

the first class belong tuberculosis, typhoid fever, and pneumonia. In pneumonia the cells of the exudate may not be all newly formed. They may have been called forth from the cell depots in the blood and elsewhere. They are, however, new in their pulmonary site and in the Abderhalden sense are out of place. To the non-productive bacterial diseases belong diphtheria and tetanus. A closer study of this classification reveals an extremely interesting point, namely, that the infections classed under (1), that is, the productive infectious diseases, are all due to bacterial endotoxins, or, in the sense of Vaughan, to split proteins, while those in Class (2), the non-productive infectious diseases, are due to the soluble toxins and not to poisons contained in the bacterial bodies.

7. Typhoid and Paratyphoid Infection in Relation to Antityphoid Inoculation, together with Remarks on the Importance of the Use of Prophylactic Paratyphoid Inoculation. G. Dryer, E. W. Ainley Walker, and A. G. Gibson.

2. Experimental Purpura.—J. C. G. Ledingham and S. P. Bedson record a series of data showing the blood changes in guinea pigs after inoculation with anti-guinea pig plate serum. The early fall in the number of platelets simultaneously with the outburst of skin purpura is found to be a marked feature. Purpura has also been produced in rabbits and rats by inoculation with the respective anti-plate serum. The blood changes in rabbits have been followed with results similar to those obtained in guinea pigs. Anti-plate serum, in addition to its purpura-producing properties, possesses in common with other cytolytic sera considerable lytic powers, which, in all probability, contribute largely towards the fatal issue in small animals. Death, however, may occur as the result of extensive hemorrhages alone without any obvious lytic changes as evidenced by hemoglobinuria. Sera obtained by immunization with red cells or leucocytes do not produce purpura. This disease is not produced by inoculating animals with heterologous anti-plate sera.

3. Shell Shock.—C. S. Myers reports three cases which apparently constitute a definite class among others arising from the effects of shell shock. The shells in question appear to have burst with considerable noise, scattering much dust, but this was not attended by the production of odor. It is therefore difficult to understand why hearing should be (practically) unaffected, and the dissociated "complex" be confined to the senses of sight, smell, and taste (and to memory). The close relation of these cases to those of "hysteria" appears fairly certain.

5. Death from Strangulated Internal Hemorrhoids.—P. Lockhart Mummery and M. J. Joshi report the case of a man, aged forty-three years, in whom complete gangrene of all the coats of the rectum occurred as the direct result of thrombosed internal piles, and believe that the condition was rendered possible by the secondary anemia from which the patient was suffering. The patient died apparently from septicemia, the result of extensive gangrene of the rectum and neighboring tissues, but had he survived longer the authors have very little doubt that the typical abscesses in the liver would have been evident. The only treatment which would appear to have given the patient any chance of recovery was an early colotomy, which would have enabled the bowel to be kept clear of fecal material. It was, however, obviously unjustifiable to perform colotomy for thrombosed veins in the rectum, and by the time it was obvious that the whole of the rectum was gangrenous it was too late for this method to have had any chance of success, while the patient was too ill to undergo any operation.

7. Inoculation Against Typhoid and Paratyphoid Fevers.—G. Dreyer, E. W. Ainley Walker, and A. G. Gibson believe that it is of the utmost importance that troops should be protected against paratyphoid infection as well as against the *B. typhosus*. This can readily be done by the use of a mixed vaccine containing equal quantities of *B. typhosus*, *B. paratyphosus* (*B*), and *B. paratyphosus* (*A*). Men already inoculated against *B. typhosus* should also be inoculated against paratyphoid infection, since the antityphoid inoculation offers no appreciable protection against paratyphoid bacilli. The epidemics of typhoid fever reported to be occurring among the belligerents (who are all known to practise antityphoid inoculation) are probably to an important extent epidemics of paratyphoid. Unless all cases of typhoid fever are properly differentiated into typhoid and paratyphoid infection the statistics regarding the value of antityphoid inoculation among the forces in the present war will be most seriously vitiated. It is probable that the absence of accurate bacteriological diagnosis in the past explains the fact that the statistical results arrived at in our army have not always been so convincing as would otherwise have been the case.

6. Serum and Vaccine Treatment of Meningitis.—J. R. Collins reports a fatal case of meningococcus meningitis in a boy aged nine years. No clinical improvement was at any time noticeable following the use of the specific serum, but on two occasions on which an autogenous vaccine was given a notable though only a temporary improvement followed.

Berliner klinische Wochenschrift.

January 18, 1915.

Nourishing the Civil Population on a War Footing.—Oppenheim concludes his serial article on this subject. He asks "how many cattle ought to be slaughtered?" This will depend upon the amount of fodder available in the future. Probably 10 per cent. of milch cows and 35 per cent. of swine will have to be killed—in figures 1,000,000 of cows and 9,000,000 hogs. The government will have to buy the animals in order to execute such a measure. The markets will then become surfeited with meat and prices will fall. An increased meat consumption will follow and the price will again rise. But measures will have to be taken to preserve a large portion of these meats. The restriction in the animal industry will be counterbalanced by the intensive cultivation of the protein-rich legumes. The crops of the latter, however, are more or less uncertain. It has been proposed to raise wheat in place of beets and potatoes and thus make up the deficit; but this again is offset by the fact that sugar beets, turnips, etc., make superior fodder. At present 14 per cent. of the farmers' horses have been

commandeered for army service, and their places must be filled by oxen and even cows for draught purposes. Motor plows will prove very useful, but owing to the scarcity of other fuel alcohol will have to be depended on. The latter is made from potatoes, so it will have to be decided by actual test whether oxen or motor vehicles are the better. A motor plow does the work of twenty-eight men and requires 300 kilos per day of starch values. The twenty-eight oxen require 400 kilos and also more human labor than the plow. A very serious problem in agriculture is that of fertilizer. While some of the mineral element is available in abundance, phosphate, and especially nitrogen, are scarce. Germany has been using phosphates which are by-products of the iron industry, and this fraction can be maintained; but imports from North Africa and the United States are cut off. Sulphuric acid for making superphosphates is also deficient. However, it is thought that enough phosphates are present in the soil to nourish the next crops. As regards nitrogen, the importation of Chili saltpeter has been abolished. The nitrogen of the air is readily utilizable in several ways, but the necessary electric power is busily engaged in other directions. But all these resources can do but little in comparison with economy in feeding. Every bit of wheat must go to make bread, not starch or alcohol. These can be prepared from potatoes, which are overabundant, and enormous fraction going to waste. But relatively little drinking spirits should be made even from these, for alcohol is necessary for fuel purposes. The author believes that the brewing industry should not be disturbed (according to recent dispatches the output of beer will be reduced one-half).

The Vita Sexualis and Warfare.—Touton presents the third instalment of his article on this subject, taking up the amount of venereal disease in the German army and navy in peace and war. In times of peace prophylactic measures have repeatedly been initiated, but it is admitted on all sides that compulsory measures against either prostitutes or soldiers cannot be enforced. To discipline a soldier for catching a disease, like all repressive measures, leads to concealment. Instead, warning against drunkenness, instruction in sex hygiene, advocation of continence as harmless, with instruction in the use of prophylactics for those who indulge, are the measures which promise most. The theater of war has always been the great breeding place for venereal diseases, as shown by the figures of all recent wars. In armies in time of peace efforts in the direction of prophylaxis appear to make themselves felt and the morbidity usually shows a tendency to decrease. Just before the Franco-Prussian war the new morbidity was at a very low figure. In October, 1870, it was 2.2 per thousand. In January, 1871, it began to rise, until in the following May it was 78 per thousand, and in certain single regiments nearly 10 per cent. were diseased. This great increase was readily explained because after the great battles at the outset the troops were engaged either in the occupation or siege of the large French cities.

Münchener medizinische Wochenschrift.

January 19, 1915.

Wounds of the Lung.—The Military Supplement of this number of the *Wochenschrift* contains five original articles on this subject. Tönniessen, who is in charge of a reserve hospital, has treated fifty-six cases, which he classifies as follows: simple injuries, 21 (uncomplicated by fever or effusion); cases with effusion of blood in the pleura, 23; cases of pneumothorax complicated by pus or blood in the pleural cavity, 8; cases of simple serous effusion, 2; cases at first sterile but ending respectively in empyema and pneumonia, 2. In the entire material there was a uniformly favorable course as to life. Böttner discusses thirty cases treated at the regular medical clinic at Marburg. The author states that developments were noticeable which so to speak were not on the program of text-book lore. There were numerous subjective symptoms. Some felt the impact of the projectile as blunt force. Others spoke of a warm sensation in the wound. Two soldiers when they were about to "hurrah" found that they could not raise the right arm (implication of brachial plexus). Short breath, hemoptysis, and pain were alike present in the majority of cases, and the latter was never absent. But aside from local distress pains were reflected or radiated in a bewildering manner—everywhere apparently, save the lower extremities. This kind of complication was due largely to actual nerve injury (brachial plexus or its ramifications). In eight patients, however, pains of this character could not be traced to nerve injuries and were treated as rheumatic with salicylic acid. A sympathetic nerve mechanism of pain did not hold water in the author's cases, but a psychic component was sometimes recognizable. An interesting symptom was abdominal tension, which is known to follow these injuries, and is believed to be due to irritation of the intercostal nerves. An explanation of certain severe cases may be found in a peritoneal reaction due to the exit of the bullet through the diaphragm. In other respects the symptoms were covered fully by text-book descriptions. Ritter describes his experiences in a field hospital without reference to the number of cases treated. Some of his conclusions are as follows: One should not wait for an empyema to form before operation. In many cases an empyema never does form. Death when it occurs is due to sepsis before an empyema could develop. An infected blood effusion is a signal for immediate operation to save life. As a general rule treatment should be conservative. The worst infections of the soft parts at the entrance opening do not justify the inference that an intrathoracic infection coexists. As a rule the reverse is the case. The pleura should be punctured repeatedly to ward off accumulation of infected fluids. As a rule the odor is sufficient for diagnosis. The external phlegmon, however, calls for the most active treatment. Conservative treatment ceases when the pleural cavity is known to be infected. As already stated, it is an error to wait for the signs of empyema to develop. Finally, if gas gangrene develop in the lung only the most radical treatment can save life. Reiche writes briefly on the natural resistance of the thoracic cavity to infection. A case is cited of a revolver shot in which, while the intrathoracic reaction was harmless, despite the presence of an extensive blood effusion into the pleura, death occurred solely from sepsis due to a phlegmon at the entrance opening. At autopsy the hemothorax was found to be quite sterile. Von den Velden has seen 107 cases of injury of the thoracic cage. In thirty-four of these the lungs were injured. The remainder involved the chest wall only. Of this number thirty-four were mild enough for dispensary treatment. Of the thirty-four pulmonary cases two were fatal (pneumonia, tension-pneumothorax). Hemothorax occurred in twenty-three of the thirty-four cases, and in sixteen cases it was acute in type. The temperature always rises in these cases without reference to infection. In ten cases there was a secondary pneumonia, due perhaps, in part at least, to preexisting bronchitis.

Hemoptysis in Young Children.—Ralleston and Robertson-Ross state that hemoptysis occurring in young children is in the majority of cases due to pulmonary tuberculosis. It is, as a rule, a sudden and fatal event.—*Clinical Journal.*

Insurance Medicine.

Life-insurance Medicine.—Professor Florschütz refers to the immense activity of the past decade in all matters relating to insurance of all kinds, and especially medical matters. The family practitioner once had the say as to who should be insured and who not. He was the sole expert and trusted by all, not only as to professional competency but in all other respects. He must have been approved of by the State, a legal practitioner who had known the applicant for years and had treated him for any recent illnesses. If an applicant had had no need of a family doctor, some physician acquaintance could be called upon by the applicant, or supplied by the district physician to serve as a health witness. Testimony was given unreservedly; the examiner stated his opinion that the risk was healthy, and the risk also signed an application in which his physical condition was considered. It represented a solution among presumably healthy people. A higher opinion was demanded only after death.

All this practice has been revolutionized. We now have confidential examiners and medical directors who review the reports of the first named. The family physician has not been eliminated, for he must often be consulted by the confidential examiner. But in place of a simple opinion by the family physician, a blank form is supplied, to be filled out by physicians known as confidential examiners, who are supposed to have a special all-around training in this line of experization. These men often draw upon the family practitioner to explain problematic answers of applicants and for other like purposes.

The medical director who passes finally on the risks has to do less with merely healthy subjects than with insurable subjects. His business is not to reject outright, but to determine how much a substandard risk can safely carry. This class of men have abundant opportunity to record their finds and ascertain the outcome, and thus supply data of prognostic value. New examination blanks can be introduced to cover particular cases. It must, however, be shown that this medical service is the best possible to maintain its own stability.—Blätter für Vertrauensaerzte der Lebensversicherung, 1914, V, No. 5.

Fatal Case of Bronchial Asthma Six Months After Insurance.—Eshenburg states that bronchial asthma for a number of reasons renders life insurance difficult, especially when the crises are frequent or severe. It then suggests organic disease of the heart or lungs or old age *per se*.

The subject was a merchant aged 25, single, was examined by the insurance company's confidential examiner, after having applied for a policy which called for the latter to mature at 55; no premium payments after 50. The examiner did not know applicant, who was of sound stock and had not done military duty but was enrolled in the Landsturm. He had never had a serious illness, and denied lues emphatically. Nothing abnormal could be found on him, but ordinary acne. Heart and lungs, likewise urine, showed nothing pathological. No emphysema nor bronchial catarrh.

The report of the confidential examiner was somewhat clouded by that of the family physician, who stated that the risk was an asthmatic and used much asthma powder. The attacks were periodical. The physical development was superb and applicant was also a total abstainer. There was, however, a history of attacks of polyarticular rheumatism without participation of the heart. For the past 7 weeks patient had suffered from sexual neurasthenia. As a result of this testimony the company rejected the application, but at the request of the agent employed a second confidential examiner, who was told the history of the case. He supported his colleagues, and even made his testimony stronger for the patient. There was no emphysema, no catarrh, the heart was normal, etc. The special opinion was "no asthma demonstrable."

Both medical directors of the company advised acceptance of the risk with possible penalties. The condition was only a simple bronchial catarrh in a young man. The case was prejudiced by the silence of the applicant in certain matters. An explanation was in order, and it was decided that neither the asthma nor sexual neurasthenia had any bearing on the expectation of life. The man was insured as substandard.

After his acceptance the patient married and six months later was found dead of "heart failure," after a nocturnal asthmatic attack. He received adrenalin and morphine during the night, but in the morning was found dead. The exact cause of death was entirely problematical. The death claim was paid.—Blätter für Vertrauensaerzte der Lebensversicherung, 1914, V, September-October.

Examining Physician as Insurance Company's Agent.—A question put to an applicant for insurance was: "Have you ever been rejected by any fraternal benefit society?" The medical examiner who put the question testified, in an action on the policy, that the applicant answered in substance as follows: "I don't know. I have applied to the Mystic Workers for insurance, but I have never heard anything from them." After consultation with two officers of the society the examiner wrote "No" in the application. So far as appeared from the evidence the applicant told the physician the truth. The court held that, under the rules of law prevailing in the State of Illinois, the regular examining physician of such a society is the agent of the society and the society is bound by his acts within the scope of his authority, notwithstanding an express stipulation in the application that the applicant makes him his agent. In Royal Neighbors of America v. Boman, 177 Ill. 27, the medical examiner asked the applicant to answer the question whether she had ever had bronchitis. She answered that she had had an attack of acute bronchitis, and the physician said that was of no consequence and wrote the answer "No." The court held that he was acting in the interests of the order and that his knowledge must be held to be the knowledge of the order. In Johnson v. Royal Neighbors of America, 253 Ill. 570, one of the questions required to be asked of the applicant by the company physician was whether she had ever had "la Grippe," and the answer "No" was written. It was proved that the application was taken by an assistant deputy, and that when that officer asked the applicant this question she replied that she had been treated by physicians and had taken patent medicines for the "grippe" and the officer said that did not count, and wrote the answer "No." It was held that the party taking the application was the agent of the society, and by his conduct the society waived its right to object to the validity of the certificate on the ground that the answers were warranties. —Turner v. Modern Woodmen of America, 186 Ill. App. 404.

Book Reviews.

The Cancer Problem. By William Seaman Bainbridge, A.M., Sc.D., M.D., professor of surgery, New York Polyclinic Medical School and Hospital; surgeon, and secretary of committee of scientific research, New York Skin and Cancer Hospital; consulting surgeon, Manhattan State Hospital, Ward's Hospital; honorary president, First International Congress for the Study of Tumors and Cancers, Heidelberg, 1906. Price, $4.00 net. New York: The Macmillan Company, 1914.

During the last few years there have been published a number of important books, varying somewhat in type, on the subject of cancer. Among these, Wolff's Lehre von der Krebskranheit is a veritable encyclopedia, with the disadvantage that it is largely a series of undigested abstracts and does not represent the views of the author himself; other volumes, such as those of White and of Ribbert on tumors and of Roger Williams on the natural history of cancer, contain valuable discussions of special phases of the tumor question; and Woglom's book on Experimental Cancer has covered the laboratory aspects quite completely. Nevertheless, there is still room for a book, like the one under consideration, which treats more fully certain of the clinical features of the cancer problem.

The first section, comprising one-third of the text, is devoted to an historical sketch, including a description of those research laboratories where cancer investigation is carried on, and a somewhat unnecessary list of names of the various workers, with a long quotation, now quite out of date, on the general nature of research and organization at the Imperial Cancer Research Fund of London, copied from the report of the Director, Dr. Bashford. This and additional rather extensive quotations from the reports of the New York Skin and Cancer Hospital might very well have been omitted as they are already accessible. Section 2 is a general discussion of the subject of the distribution of cancer in animals. Section 3 reviews the statistics of cancer, these being supposed to demonstrate an increase in the incidence of cancer in certain regions or organs, while in others, for instance the skin and the uterus, no increase has occurred, according to the English statistics, which are the most reliable of those now available. The important work of Murray on the increased occurrence of cancer following concentration of cancerous ancestry in mice is also referred to. The various theories as to the nature of cancer are next summarized, the conclusion being simply that no theory in any degree offers a complete explanation.

The section on the histopathology of cancer is illustrated by a series of excellent drawings showing the various types of human carcinoma and sarcoma. The more theoretical part of the book is largely derived from the publications of the Imperial Cancer Research Fund and is illustrated by some of the excellent cuts from monographs appearing from that laboratory, though the familiar groups of Kashmir natives need not have been reproduced both as a frontispiece and on page 66. The remainder of the text is concerned chiefly with diagnosis and the clinical aspects of the disease and with a discussion of the measures which have been applied to its treatment. It may seem strange that it should be considered necessary in a work of this character to refute the therapeutic claims of cancer cures such as turpentine, molasses, and violet leaves and other plant juices, but any one who sees many patients with malignant disease knows that even to-day a considerable portion of the incurable cases coming to hospitals have been treated, often for months, with these or similar remedies. The writer has done valuable work in summarizing the refutations of the claims of such hypothetical cancer cures as the trypsin method advocated by Beard, the various sera and bacterial extracts and toxins, the tissue emulsions and vaccines made from cancer cells, and the products of tissue autolysis—all of which have been shown again and again to have no curative effect. This portion of the book is extremely useful, not only for the lay reader but also for those practitioners whose time and knowledge of foreign languages are not sufficient to permit them to follow the publication of recent experimental work. Another excellent feature is the thorough review of the operative treatment of late cases in which the ligature of vessels and special technical procedures may possibly prolong life, the cases being otherwise regarded as incurable. Still another valuable section is that on the methods and results of the attempts at popularizing our present knowledge of the nature of cancer and the necessity for early diagnosis and prompt operation. An extensive bibliography and a well arranged and complete index end this useful volume. Unfortunately, the text is marred by numerous typographical errors which will, no doubt, be corrected in another edition.

Carcinoma of the Thyroid in the Salmonoid Fishes. By Harvey R. Gaylord and Millard C. Marsh. Publications from State Institute for the Study of Malignant Disease. Serial No. 99. Issued April 22, 1914. Washington: Government Printing Office.

This U. S. Government Report contains over 500 pages of text and 127 illustrations, mostly micro-photographs. Works of this type are hardly amenable to ordinary reviewing. Summaries and conclusions in English, French and German are appended, but these possess but little interest for the student of human cancer. The conclusion is reached that in the trout endemic goiter and carcinoma of the thyroid are one and the same disease, which in all probability is due to a living organism. The disease, however, is not known to pass from one animal to another. It occurs in trout in the state of nature but becomes endemic in hatcheries; certain species, however, showing high degrees of immunity. Likewise we see at times spontaneous recovery with acquired immunity.

Reducing Weight Comfortably, the Dietetic Treatment of Obesity. By Prof. Gustav Gaertner, M.D., Vienna. Authorized translation in English. Price, $1.50 net. Philadelphia and London: J. B. Lippincott Company, 1914.

With the experience gained from the completion of two thousand obesity treatments, this author here describes his method for the reduction in weight of those who are too fat. There is nothing startlingly new in his methods. "No obesity cure without dieting. Only by dieting is success always obtained." These are the basic principles of his treatment. The diet he recommends is restricted in quantity rather than in quality and is so planned as to reduce the patient's weight by from 0.15 to 0.2 per cent. per day. The treatment is described in considerable detail and several cases cited. Of the efficacy of such a treatment as he proposes there can be no doubt provided, of course, that it be directed and followed with sufficient enthusiasm. The translation rather accurately presents the spirit of the original.

The Heart in Early Life. By G. A. Sutherland, M.D., F.R.C.P. Senior Physician to the Hampstead and Northwest London Hospital. Physician to Paddington Green Children's Hospital. Price, $2 net. London: Henry Frowde, Oxford University Press. Hodder and Stoughton; New York: The Oxford University Press, 1914.

It is not very many years ago that little was known concerning the heart of a child, that is, from the medical scientific standpoint. The subject was not mentioned in text-books dealing with the diseases of children. Gradually, however, the conviction has been forced upon practitioners that in many essential points, the heart in early life differs from the adult heart. Dr. G. A. Sutherland in the book now being noticed, has dealt with certain clinical problems of cardiac disturbances and diseases during childhood and youth, as they present themselves in the ordinary routine of practice. The author refers to the fact that the scheme of the book is directly due to the discoveries regarding the heart and the teachings thereon by that great pioneer in scientific cardiology, Dr. James Mackenzie. The volume is timely as it provides a clear exposition of modern scientific views with respect to the heart in early life.

Air, Water, and Food from a Sanitary Standpoint. By Alpheus G. Woodman, Associate Professor of Food Analysis, and John F. Norton, Assistant Professor of Chemistry of Sanitation; Massachusetts Institute of Technology. Fourth Edition, Revised and Rewritten. Total Issue Five Thousand. Price, $2.00 net. New York: John Wiley & Sons, 1914.

In this volume will be found a discussion of the three essentials of life, namely air, water, and food. Clean air, safe water, and good food are necessary to health and comfort as well as to life; and they are therefore subjects of vital importance to every one. The present work is elementary rather than exhaustive, and it contains a useful bibliography of the more important of the recent publications on the same subjects.

Society Reports.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held December 1, 1914.

THE VICE-PRESIDENT, DR. E. G. ZABRISKIE, IN THE CHAIR.

Brain with Double Frontal Abscesses.—Dr. L. CASAMAJOR reported this case and showed the specimen. The history was furnished by Dr. E. J. Smith of Larchmont, N. Y. The patient was a mechanic and inventor, fifty years old, whose family history was negative. Between the ages of twenty and thirty he had suffered from several severe attacks of articular rheumatism, with heart complications. The patient had always been very active as a young man, and at one time was a long distance bicycle rider. Until about twenty years ago he used alcohol habitually and to excess, but for fifteen years preceding his death he had been a total abstainer. He smoked constantly and used chewing tobacco daily. During the past ten years he had worked very hard at his trade and had accomplished a great deal in a mechanical line. He took no recreation excepting a few days each summer, when he did some yacht racing. The exact date of the onset of his present illness could not be fixed. He was in the habit of receiving osteopathic treatment for minor ailments, and was under the care of an osteopath when he came under Dr. Smith's observation on March 10, 1914. At that time the patient complained only of a slight frontal headache and of being unusually tired. He had the appearance of being slightly jaundiced. The pupils were contracted, reacting slowly. The tongue was heavily coated and the breath offensive. The temperature was normal; pulse, 60 per minute and full. On his first day in the hospital he refused to stay in bed; he wished to go to business and insisted on smoking his pipe. On the following day he kept his bed and abstained from tobacco. He remained in his usual jovial mood and his symptoms were such as one would expect in a case of catarrhal jaundice. His condition remained practically unchanged for four days, without improvement in appetite, appearance of tongue, etc., in spite of active purgation. On the fifth day it was observed that he was quite indifferent to his surroundings and very talkative. His headache had disappeared almost entirely and he still had nothing to complain of. When left alone he talked and whistled, and was not at all disturbed when he soiled the bed by an involuntary defecation. His pulse remained slow, and his rectal temperature on the fifth day was 101°. The urine was stained deeply with bile; it contained a trace of albumin; no sugar; there was a marked indican reaction and a few hyaline casts. No complete blood count was made, but a differential count showed 79 per cent. polynuclears. The stools were offensive and lighter in color than normal. The pupils remained contracted and sluggish, acting equally. The ears showed nothing abnormal and there was no nasal discharge. The patient remained in practically the same condition for another twenty-four hours, appearing indifferent when he was alone, but acting quite rational upon being questioned. There was no paralysis and the reflexes were normal, excepting the pupillary. His temperature on the evening of the sixth day was 101° in the rectum; pulse, 54; respirations, 18. At 8 A. M. on the seventh day after his admission he suddenly developed a chill, his rectal temperature rose to 106°, he became comatose, developed Cheyne-Stokes respiration, and died in three hours.

Two days prior to this patient's death his family was advised that the symptoms pointed to some unusual brain lesion, the exact nature of which was not clear.

Autopsy.—The brain was removed, and upon its removal about half an ounce of foul smelling pus escaped through the right frontal lobe. Further exploration showed a double frontal abscess, undoubtedly primary on the right side, and extending through the corpus callosum into the left frontal lobe. No other abnormality was found. There was no pus in the ventricles; no internal hydrocephalus. The pus found in these abscesses contained the *Bacillus pyocyaneus*. The infection from this organism, Dr. Casamajor said, was, according to Oppenheim, most often hematogenous and was one of the commonest causes of brain abscess. The meninges in this case, as well as the frontal and other sinuses, showed no evidence of involvement.

Pavor Nocturnus.—Dr. A. STERN reported two cases. The first case was that of a girl, eight years old, the youngest of seven children. The mother of the child was markedly neurotic; otherwise the family history was negative. This child had always been her mother's pet, rarely leaving her side and without any desire to play with other children. She cried bitterly when her mother went anywhere without her. She had always been fed, dressed, and bathed by the mother, who had noticed that while bathing the child, when the hand came in contact with its genitals, the child would press the mother's hand between its thighs. This, Dr. Stern said, we might consider a sexual trauma, as surely we could interpret the child's action in no other light than a desire to prolong the contact, and in this way a desire of a distinctly sexual nature was directed by the child toward the mother. Naturally the child desired to be, whenever it could, in the presence of its mother—its loved object, and this was easily enough accomplished by day, while night terrors, from which the child frequently suffered, served the purpose at night. Night terrors were very properly so called, the speaker said, not only because the children, during the attacks, had such an expression of dread and anxiety on their countenance, but also because these attacks produced terror in the members of the family, and it was through the latter that the child gained its object, namely, to have some one with it at night. In this case, as in the second case reported, the children were cured of their terrors when the mother was instructed to insist upon their sleeping alone and paying no attention to them when the attacks occurred. The children were also taught to rely on themselves, to become less self-indulgent, and to spend more time in the company of other children. Dr. Stern said that the practical application of the knowledge gained from Freud's teachings perhaps nowhere else showed such rapid and brilliant results as in the treatment of the different manifestations of the neuroses as they occurred in children. Stekel held the view that the most common form of neurosis that existed in children was the anxiety neurosis, and a very frequent manifestation of this neurosis, and heretofore very difficult to treat, was the night terror. The causes of pavor nocturnus, as heretofore given, were about as follows: (1) adenoids and enlarged tonsils; (2) large and irregular or indigestible meals eaten before going to bed; (3) terrifying stories told to children before retiring. In answer to a question as to how the treatment in these two cases differed from that employed heretofore, Dr. Stern said that Holt, in his book, recommended that in cases of night terror where children were very much frightened, some one should be in the room with them, which was directly opposed to the treatment employed in these cases. Drugs had also been recommended, among them bromides.

A Case of Vagotonia.—Dr. WALTER TIMME presented this case, in connection with which he gave a brief survey of the divisions of the autonomic nervous system, in which he mentioned some of the characteristics of an over-active extended vagus, and which were manifested in this patient, such as hyperacidity, hypermotility of the stomach, vomiting, constipation with occasional diarrhea, bradycardia, low blood pressure (105-110 mm.), dermatographism, absent gag reflex, clammy hands and feet, and cessation of menstruation. In striking contrast to these symptoms were those of a marked sympathicotonia, namely, mydriasis and wide palpebral fissures. The patient was an unmarried woman, 29 years old, who was engaged at social service work. Of some importance in her family history was the fact that two members of her mother's family had suffered from attacks of spasmodic asthma for twenty years. This patient, following a succession of mental shocks in the spring of 1911, began to vomit after each meal, and this daily vomiting had persisted without any lapse up to the present time, a period of over three years. Eight years ago she had a similar attack which lasted three weeks and ceased spontaneously. The excessive motility of her stomach musculature was proven by two roentgenograms, showing that the stomach emptied itself of bismuth paste in twenty minutes. One of these plates showed very well the condition of the spastic stomach wall termed by Holzknecht "Cow-horn" stomach. It was found that the patient could retain some articles of food, notably chocolate, for a much longer period; perhaps this was due to the slightly sympathetic stimulant theobromine which chocolate contained. As the patient was not willing to give up her work, the treatment with atropine could not be carried out very satisfactorily; so unsatisfactorily, indeed, that

the small doses of the drug that had been given seemed to bring out a greater opposition on the part of the vagus, increasing some of her symptoms. Various combinations of glandular extracts had been tried with very little effect. The patient had also been under psychoanalytic treatment without any success. In reply to a question, Dr. Timme said the patient could retain coffee, if it was strong. As to whether an intrathoracic-thyroid could be ruled out in this case, the speaker said it could not. Vagotonia might be a disease entity, or it might accompany any of the toxic conditions.

Dr. S. Rothenberg of Brooklyn said that in the article by Eppinger and Hess on this subject, the authors suggested that it was sometimes possible to bring out an entire train of symptoms by the injection of a small dose of pilocarpine, and the aggravation of certain symptoms thus elicited might act as a guide in the subsequent therapy of the case.

Dr. D. M. Kaplan referred to the work of Fleischmann in the Hess Clinic, who came to the conclusion that it was absolutely impossible to classify these cases, owing to the fact that one group of symptoms corresponded to the vagotonic condition while another corresponded to the sympathetic. For example, the dilated pupil had been explained by Eppinger and Hess as due to the presence of excessive adrenal secretion in the blood, and he advised certain tests for ascertaining the amount of adrenal secretion.

Dr. Timme said the pilocarpine test mentioned by Dr. Rothenberg was only useful in cases where the irritability of the vagus was in doubt. When the vagotonic symptoms were present, the pilocarpine test was unnecessary. As a matter of fact, pilocarpine had been tried in this case and had aggravated the vagotonic symptoms. The speaker said he had seen no instance in which all the symptoms were either wholly vagotonic or sympathetic, and he knew of no one else who had reported a pure case of vagotonia.

Dr. I. Abrahamson thought the word vagatonia was a misnomer in these cases, as the vagus was a very complex bundle of nerves, made up of mixed fibers, including both accelerator and depressor fibers to all the viscera. It would be preferable, he thought, to speak of these symptoms as being derangements of either the autonomic or sympathetic systems and to drop the word vagotonia altogether.

Pain and Tenderness in Spinal Disease and Its Surgical Treatment.—Dr. Charles A. Elsberg read a paper on this subject and showed a number of cases and a series of lantern slides to illustrate the peculiarities in sensory disturbances observed on patients in the course of 100 spinal operations. He emphasized the fact that there was a marked difference between the cervical and the dorsal spinal roots in their structure as well as their course. The cervical roots originated from the cord over an area one to two centimeters wide and ran as separate bundles to the dura, while in the dorsal region the bundles soon united to form one nerve root. Therefore, in the cervical region, a tumor could press on a few of the root bundles and give rise to symptoms from those bundles only, so that one should differentiate between root bundle symptoms and root symptoms. He reported several cases in which pressure upon the lower root bundles of the seventh cervical posterior root produced pain limited to the index finger, so that it was probable that the lower root bundles of the seventh cervical nerve supplied the index finger and perhaps part of the middle finger. Dr. Elsberg then described the peculiar course of the nerve roots. In the dorsal region the roots first ran downwards, bending upwards again at a very acute angle. Further investigation had shown that the outer surface of the dura of the spinal cord was very sensitive, while the cord itself was insensitive excepting near the origin of the posterior roots, and the posterior roots themselves were very sensitive. Taking these facts into account, it was easy to understand how a small focus of malignant disease in the posterior and lateral surface of the body of a vertebra could cause very acute root pains. Extramedullary tumors which did not press upon nerve roots might cause pain in the back from pressure on the inner surface of the dura, especially if they laid in front of the slip of the dentate ligament. The reader then described a peculiar set of symptoms which he had observed in several cases of extradural tumor. There was a kind of reverse Brown-Sequard, the motor symptoms being on the opposite side and the sensory symptoms on the same side as the tumor. In these cases there was a collection of fluid under the dura on the side of the tumor, which pressed the spinal cord to the opposite side against the walls of the spinal canal, so that the motor symptoms were due to the pressure of the contra-lateral pyramidal tract against the bony wall of the canal. This could be called *contre coup*, and was similar to what occurred in the posterior cranial fossa when a cerebellar tumor of one side pushed the cerebellum to the other side and caused the facial nerve of the contra-lateral side to be pressed against the petrous portion of the temporal bone, with resulting facial paralysis on the side opposite to the lesion. Finally, he reported peculiar anomalies of the spinal vessels which gave rise to irregular symptoms and which had not hitherto been described. These cases, he said, deserved further study. In order to illustrate the facts of the paper, Dr. Elsberg presented the following cases:

Case I.—A patient who was completely relieved of symptoms of abdominal pain on the right side by the removal of an extramedullary spinal tumor from the 12th dorsal segment.

Case II.—A patient from whom a tumor had been removed at the 8th dorsal segment, underneath the slip of the dentate ligament. This tumor had caused paraplegia and severe pain in the back.

Case III.—A patient cured after removal of a tumor from the eighth cervical segment. She had suffered from marked motor symptoms for a long time, but sensory symptoms only appeared after lumbar puncture had been done.

Case IV.—A patient who rapidly recovered from a paraplegia of three years' duration after the removal of a small tumor from the sixth cervical segment. This patient at first presented symptoms at the eleventh dorsal, but a laminectomy failed to discover the tumor. A year later, the patient presented level symptoms at the first to second dorsal, but the tumor was found at the sixth cervical.

Case V.—A patient who had had spastic paraplegia due to a localized pachymeningitis, with tremendous thickening of the dura at the sixth dorsal level who was completely relieved by excision of the thickened dura.

Case VI.—A patient completely relieved for a number of years by decompressive laminectomy from symptoms simulating mutiple sclerosis.

Case VII.—A patient with acromegaly who had had an acute exudate in the sella turcica, causing the rapid development of eye symptoms. When the patient was admitted to the hospital he had meningeal signs, was blind in the left eye, and had temporal hemianopsia in the right eye. With the subsidence of the hypophysitis or perihypophysitis, the fields of vision in both eyes gradually returned to normal.

Dr. I. Strauss, discussing the last case shown by Dr. Elsberg, said that when he saw this patient, together with Dr. B. Sachs, he was in a condition of stupor. He had previously ben examined by Dr. Abrahamson, who was then able to make out a hemianopsia in one eye, but when Dr. Strauss saw him the patient was not sufficiently conscious to answer questions. He had then been in the service of Dr. Morris Manges for about a week with a temperature curve very suggestive of typhoid fever, and an examination of the blood showed the presence of the paratyphoid bacillus. He had been suffering for some time from a profuse and offensive nasal discharge. There was increasing stupor and coma, with a slight Kernig's sign, and some stiffness of the neck. Repeated lumbar puncture gave clear fluid and no increased leucocytosis; hence it seemed certain that there was no meningeal process. There was a history of trauma eleven years previously (falling from a considerable height) followed shortly afterwards by enlargement of the hands and changes in the face characteristic of acromegaly. The acromegalic features of the case were regarded as due possibly to a cyst or some other disturbances of the hypophysis. The acute symptoms were regarded as being due to ethmoidal or sphenoidal disease, possibly of paratyphoid origin, though this was not proven. Dr. Emil Mayer was then asked to see the case, and he felt somewhat loath to expose the sinuses on account of the general blood infection, but he was finally convinced that there was no reason why a local focus of infection of this kind, provided it existed, should not be treated just as is done in bacteriemia due to sinus thrombosis in atitic disease. He thereupon opened the themoidal cells and drained them. From that time on the patient's improvement set in, and on the very next day his mental condition was much better. It was possible to rouse him, he answered questions intelligently, and his temperature gradually reached normal by lysis. At the same time the remark-

able improvement in his sight, which Dr. Elsberg had shown by his charts, developed. This case, Dr. Strauss said, seemed to him to present an infection of the sinuses, with secondary involvement of the chiasm. The rhinologist not infrequently saw cases of sinus disease, ethmoidal or sphenoidal, with optic neuritis which might go to blindness, if unrelieved, and the emptying of the sinuses was always followed by a rapid return of vision and lessening of the inflammation of the optic nerve. The speaker said he did not see how the symptoms in this case and their rapid disappearance after operation could be interpreted in any other way. One could be almost certain that there was no meningeal involvement, as proven by the fact that the spinal fluid was clear and that recovery was so speedy.

Dr. L. Hauswirth, who had seen the case in the service of Dr. Morris Manges at Mt. Sinai Hospital, said the sequence of symptoms in this case were rather remarkable, and they finally led to the conclusion that we had to deal with a sinus infection in a patient with acromegaly. The man gave the history of having fallen from a four-story building ten years ago, and that he grew tremendously after that. When he was admitted to the hospital he stated that for the preceding ten days he had noticed that the sight of his left eye was becoming dimmer and was gradually lost. He then became unconscious, although when Dr. Abrahamson saw him, after withdrawing 30 c.c. of spinal fluid, he was able to demonstrate a temporal hemianopsia on the right side and complete blindness on the left. The question naturally arose whether the fall might not have resulted in a hemorrhage, with the formation of a cyst. A peculiar odor was noticed about his bed, and we found a very offensive discharge from both nostrils, particularly from the right. Dr. Emil Mayer's operation on the ethmoidal cells was followed by an immediate improvement in the left eye; and within twenty-four hours he had a bitemporal hemianopsia which soon disappeared. The failure of the hemianopsia to persist proved either that he had had no cyst at all, or that it had disappeared—an unlikely alternative. That the infection of the sinus in this case was of parathyroidal origin, Dr. Hauswirth said, had not yet been proven.

Dr. J. Ramsay Hunt said it was certainly a great pleasure to listen to a surgeon who had had the opportunity of seeing these lesions in the living subject, and who was able at the same time to discuss them from the viewpoint of the neurologist. Among the lesions described by Dr. Elsberg was an enlargement and varicosity of the veins of the pia mater, which corresponded in level to the distribution of the symptomatology. In such a condition, the natural presumption would be a secondary congestion of the venous circulation from pathological changes within the spinal cord itself. In this connection it was of interest to recall the rare occurrence of varicose veins of the sciatic nerve (*sciatique variquese*). Speaking of the vertebral pain associated with spinal tumors, Dr. Hunt said he had always explained this on the basis of a localized meningeal irritation. This pain, in his experience, was usually bilateral, and had not the unilateral distribution of the root pains. He thought it well that Dr. Elsberg had emphasized the importance of cutting the posterior root where it had been subjected to pressure for a considerable length of time, and in that connection he asked his opinion as to the advisability of cutting these roots for the relief of a long-standing unilateral spasticity, when the site of operation exposed the necessary root distributions. The possibility of contralateral pressure symptoms occurring in connection with lesions of the cord, as shown by the reader of the paper, was of extreme interest. The mechanism of contralateral pressure was recognized as a rare occurrence in the hemispheres of the brain and also in the brain stem, in which event its recognition would be of great importance from the operative standpoint.

Dr. I. Abrahamson said he had seen two cases where marked changes of the vessels of the cord were present. The specimens had not yet been carefully examined in order to determine whether they found the beginning of an angiomatous condition and a true varix. One specimen did not show any dilatation of the vein—only a moderate hyaline degeneration of its walls. These cases were quite typical in their symptoms, and were in sharp contrast to those common to extramedullary tumors of the cord. In the latter, the motor symptoms were markedly predominant, with root symptoms at the level, while the cases with varicose vessels showed a marked preponderance of the sensory symptoms, the motor symptoms never equalling the sensory in their intensity. The finding of this dilated blood vessel at the exact level and position that was indicated by the signs and symptoms left but very little doubt as to its etiological importance. When one had to deal with a rather atypical level cord picture suggesting an intramedullary lesion and yet not characteristically so, associated with slight motor symptoms and marked sensory symptoms, one should be on the lookout for this condition of varix or a type of angioma of the cord.

Dr. Foster Kennedy said that apropos of angioma of the cord producing symptoms referable to the interior of the cord rather than to pressure upon the outside of the cord—that is, intra- rather than extramedullary—he thought it well to bear in mind that a chronic syphilitic pachymenigitis of long duration very frequently produced such circulatory conditions, usually by nipping of the blood vessels, as to cause a breaking down of the interior of the cord, so that we had to deal with a syphilitic syringomyelia. He asked Dr. Elsberg whether heregarded these symptoms as being due to the direct pressure of the varix or to the circulatory disturbance produced thereby; in other words, whether the symptoms were mechanical or circulatory.

Dr. H. Climenko said he had had the opportunity to observe two of these cases in the service of Dr. Abrahamson. In one of them the symptoms closely simulated multiple sclerosis; the sensory symptoms made their appearance later. In the second case he saw the symptoms were also very puzzling for a long time, and as it subsequently was shown, the sensory symptoms did not correspond to the location of the tumor. Moreover, there was no constant level, the symptoms shifting up and down. The motor symptoms in this case were so far advanced that even if a tumor had been found, no such improvement as actually occurred would have been expected.

Dr. S. P. Goodhart said that in one of the cases which he saw, the patient gave an early history of paresthesia affecting the thumb and index finger of one hand. It had since occurred to him, the speaker said, that it was very likely that some of the fasciculi of the cord were affected at that time.

Dr. Alfred S. Taylor said that one must be careful lest we attribute too much importance to the presence of these varices. There was a considerable space between the cord and the dura, and he could recall several cases where he had observed large veins in this location, and where a simple decompression had given perfectly satisfactory relief, the condition probably being one of inflammation in the cord and the enlarged vessels being an expression of such inflammation.

Dr. Elsberg, in closing, replying to Dr. Hunt's question as to the advisability of cutting the posterior nerve roots for the relief of spasticity, said he would only advise such a step in cases where the cord had been subjected to pressure for a long time, perhaps four, five or six years, and had been injured beyond the hope of recovery. As to the significance of these enlarged vessels, he felt convinced they were not the ordinary congested vessels one found accompanying an inflammatory process. In the condition he had described, the veins were from six to eight times their normal size—larger than the radial artery, and at once impressed the operator as enormous vessels of abnormal size. In 114 spinal operations, he had only observed this peculiar enlargement six times; ordinary slight inflammatory enlargement he had seen many times. His object in showing these cases was to call attention to this peculiar anatomical condition that so far as he knew had not been described elsewhere.

Some Psychological Studies on the Nature and Pathogenesis of Epilepsy.—Dr. L. Pierce Clark presented a paper on this subject. He first referred to the contending views whether genuine epilepsy was a true, degenerative organic disease of the cerebral cortex, or a neurosis in its true sense, a functional disease of the nervous system without demonstrable or constant lesions. Both of these views had their strong points and possessed their special advocates. Suffice it to say that probably less than one-half of all cases of genuine epilepsy had a generally acknowledged gross or microscopic pathology or constant lesion. On the other hand, the chemotoxic theory of the disease had even less positive evidence to offer. Even the experimental use of these toxic agents did not produce constant convulsive symptoms. Epilepsy, as we knew it clinically, could not be experimentally induced. There was always something lacking. In view of the present unsatisfactory anatomic pathology of the disease

and an equal failure in chemotoxic pathogenesis, it behooved us to study the clinical make-up of epilepsy more closely. With this view in mind, Dr. Clark said he undertook two years ago to analyze the epileptic temperament and character before the convulsions had occurred. Obviously, cases for such a study had to be selected from those individuals who were already epileptic, but in whom it was possible to study the developmental traits of character before the convulsive part of the disorder had developed to complicate the personality make-up. Some twenty-five cases had now been analyzed carefully by this method. First of all, cases of feeble-mindedness were absolutely excluded, and the majority of those selected were often above their grades at school. The following was a summary of his findings: It was found that the potential epileptic, as a rule, possessed a supernormal output of energy which was constant and fairly productive of good developmental results as far as the organic make-up was concerned. There was a poorly repressed or thinly inhibited outcropping of the egotistic tendencies. These characteristics of a pathological self-love were far beyond the bounds of a pure physiological variation. As a rule, the potential epileptic was illy adapted to his environment and could not easily change the same. He cooperated badly in social and economic settings. For the most part he was frank; the subtleties of mind were not his; on the contrary, he had a simple, childlike pattern of emotional life. He never had the scruples nor doubts of the obsessive neurotic; not being hindered with the inhibitions and prohibitions of the latter class, he was often permitted to become engrossed with the lower animal instincts and passions. With the inhibitions reduced and with an over-emphasized estimate of his own importance and ability, the potential epileptic found himself in constant conflict with the outside world. While the normal individual had his infantile struggle with reality and made the life compromise, the potential epileptic youth kept up the baffling strugle; hence his deep-rooted dislike and even hate of the outside world. Individuals who possessed the epileptic constitution lacked real general interests. The libido was rigid, self-centered and crude. There were small religious promptings; the meaning and ends of life rarely engrossed the potential epileptic. His friendships were perfunctory; the egotistic traits prevented a free range of emotional expression. A parental attachment of the potential epileptic to his own sex was the rule, and this was especially marked in girls. The love fixation to the mother in the majority was prominent more or less throughout life. The potential epileptic's attitude toward the opposite sex was very significant; it rarely possessed the higher love attributes and more frequently evolved little beyond the simplest or grossest sexual demands. That fact alone, independent of the superadded convulsive disorder, made marriage among epileptics almost invariably a failure. For some time now it had been customary for psychiatrists to ask themselves What do psychotic individuals get out of their disease? What purpose do the mental symptoms and settings serve to the unconscious and instinctive demands of the person so afflicted? Such studies had compelled the investigators to discard much of the conscious formulation of the obvious content of the psychosis and look more deeply into the unconscious strivings as shown in the symbolic utterances and behavior of their patients. With this altered approach to mental disorders a new era dawned in psychiatry; mental symptoms once discarded as meaningless or unimportant took on a new significance and interpretation. From the inspiration of such work, Dr. Clark said, he undertook to study anew the meaning of the fit in epilepsy, a work now some two years old. He now had the material of a dozen or more cases of genuine epilepsy, an epitome of the findings of which he briefly set forth. Uniformly in all cases it was found that the fit served as an unconscious gratification to the libido. By dream analysis, the analysis of many minor attacks, and of a few major fits, this unconscious striving was often found to be a sexual outlet; in others it was a discharge of accumulated pleasure affects that had been long accumulating in the individual epileptic. The essential motive in all genuine epileptic fits would seem to be at bottom an unconscious striving on the part of the epileptic to return to intrauterine life and was conditioned upon the stage of libido fixation in infancy, which occasionally might be so advanced as to reach into homosexuality but rarely into heterosexual life. Finally, we had more or less definitely indicated what the motive of the unconscious mechanism of the fit really was, but how might we account for the nature and character of the classic but peculiar type of muscular spasm in the grand mal seizure? At another time, Dr. Clark said, he hoped to give a detailed comparative study to show that the types of muscular movements were from that infantile period to which the unconscious urge strives to force the unconsciousness to return, namely, the intrauterine period and possibly the first few months of extrauterine existence. The seizure movements were point for point identical with the impulsive movements of the fetus and the period of earliest infancy. In the normally developing child these muscular movements were slowly but definitely repressed as the will and the conscious life unfolded; in the epileptic the impulsive movements of earliest infancy were released from conscious and voluntary control, and they re-enacted the fetal and infantile purposes of satisfaction of that period. Lastly, the speaker referred to the enormous therapeutic gain we might obtain in looking at the epileptic mechanism in the light of the therapy briefly set forth in his paper. The hygienic training treatment, the educational and environmental therapy were given a new and clearer meaning by this hypothesis; it signally made clear the reasons for the large majority of epileptics who could not be cured, and at the same time it showed a much more definite and speedier plan by which we might rescue the less severe cases of epilepsy by restoring them to health as shown in an arrest or cure of epileptic fits.

Dr. Hoch said the most prominent feature which Dr. Clark's study brought out was that in epilepsy, as in the psychoses and neuroses, that which one might call infantile motives played an important rôle. Such infantile motives were the result of imperfect development of the instincts. Such motives Freud had demonstrated in the neuroses by means of his psychoanalytic method. In psychoses they were very prominent and quite plain. They expressed themselves often in delusions and hallucinations of the patient, which we did not understand formerly because the patient did not produce them in an adult logical form, and because we had no idea of the fact that a defective instinct development could give rise to such motives. But once this was known many of the utterances of the insane became strikingly clear and did not require the complicated, difficult, and, in the hands of the inexperienced, doubtful method of interpretation because the patients very plainly expressed these infantile desires. The interesting personality studies on epileptics which Dr. Clark made also gave us, as all such studies did, an interesting confirmation of the claim that epileptics presented imperfectly developed instincts. But one could hardly admit the claim that in patients with constitutional disorders there was an all-engrossing attachment to the parents into which even sexual elements entered, although the matter became very convincing when we found that this motive returned with almost tiresome frequency in the delusions and hallucinations of the psychoses. Still more absurd seemed at first glance the desire to get back into the mother's body, but when looked at from the point of view of a desire for complete shelter, for that most fundamental renunciation of adaptation to reality, it appeared much more reasonable, and the special formulation which we found in delusions and in dreams, namely, a formulation which often referred to the real womb, was likely to be in large part a secondary mental elaboration. At any rate this motive had to be accepted as a definite fact, no matter how we tried to explain it. This entire method of studying diseases had added much to our knowledge of the symptom analysis, the structure of the clinical factors, and the forces at work. It should, of course, not be claimed that the forces thus discovered and the imperfect instinct development were the final cause of epilepsy. Such studies gave no account, and did not claim to give any account, of the organic causes of the constitutional defect or the organic side of abnormal functioning of the instincts.

Dr. John T. MacCurdy thought that all those who had studied epilepsy with psychonalytic methods would admit that Dr. Clark's paper marked the most important advance in our knowledge of the subject. We knew from our data—pathological, clinical, and hereditary—that epilepsy occupied a lower scale in mental adaptation than did dementia præcox. In the latter the essential feature was the attachment of the patient to the parent of the opposite sex. This already implied a certain degree of interest outside the individual, a certain degree of objectivation. If epilepsy represented a

lower stage in adaptation then we should look for the point of fixation in the stage of "mother-life," and that Dr. Clark had apparently discovered. He had told us that epileptics were intensely egotistical, which pointed to a failure of objectivation; that the conflicts of the world were nothing to them, which was another evidence of egotism, and, finally, he had made the very interesting observation that there was a definite desire to return to the mother's body. That was an extraordinary claim, yet we saw it in other psychoses. The speaker said he recently saw an epileptic who claimed that during his convulsion he went back to his mother's womb, which he very much enjoyed.

Dr. Smith Ely Jelliffe said that the "mutterleib's phantasy" was met with in various phenomena in addition to the epilepsies, such as in various conversion and compulsive phenomena. Dr. Clark apparently would apply a general situation present in the psyche of all individuals as explanatory of a specific phenomenon. It would be of practical interest in the analyses of the epileptic phenomena to see just how the individual had evolved the universally present Œdipus situation through the individual muscle erotic gratification. It was no solution to say that these patients showed an introversion type in phantasy—everybody did that. The answer should show how the epileptics worked out their phantasy not in harmonious muscular activity but in the discordant and nonadaptive epileptic discharge.

Dr. Clark, in closing, said he had not included the definitely organic cases of epilepsy in his study, and that for the time being he wished to limit his interpretation of the mechanism of epilepsy to that of the so-called idiopathic group. He might say, however, that he had seen several cases of epilepsy which followed in the wake of infantile cerebral palsy in which the mechanism of the attack was quite identical with those he had studied in essential epilepsy as embraced in his paper. He cited the fact that Binswanger, Gowers, and Oppenheim had all indicated that the essential make-up in personality and the enduring mental stigma of the disease were to all intents and purposes identical in epilepsy following cerebral palsies as compared with that of idiopathic epilepsy. From this and other data in his hands he was willing to admit that the possible real genesis of the epileptic state might be organic at bottom. But where persistent attacks occurred his contention was that the organic insult merely permitted or allowed the mechanism of epilepsy to occur as he tried to show it to have done in his study.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 10, 1914.

Dr. William P. Northrup in the Chair.

Presentation of Cases Showing the Effect of Blood Transfusion in Purpura Hemorrhagica, Henoch's Purpura, Chronic Sepsis, etc.—Dr. Edward Peterson presented these cases. He stated that all types of pathological hemorrhage yielded the best results when treated by blood transfusion, or by subcutaneous injections of human serum. Of the two methods the former had proven the more efficacious. Following transfusion there was an increase in blood pressure, in the number of cells, and in the percentage of hemoglobin, and the coagulation time was shortened. Besides being hemostatic, whole blood, administered by transfusion, stimulated the hemopoietic functions and there was an increasing clinical evidence that it was also antitoxic and bactericidal. The effects of blood therapy were well illustrated by the following cases.

Case I.—This patient, 4½ years of age, was admitted to the Post-Graduate Hospital on April 16, 1914, with purpura hemorrhagica. The child was normal at birth and had been well since, with the exception that he had had measles at the age of one year. A few days before admission to the hospital he began to bleed from both ears and from the nose, but not from the gums, mouth, or throat. A petechial rash appeared on the feet, legs, hands, and arms. Later large ecchymoses appeared on the eyelids and under the eyes, and then on the thighs and legs. There were small ecchymotic spots on the body also. The blood count showed red blood cells 4,300,000; hemoglobin 68 per cent.; leucocytes, 16,200; polymorphonuclears, 74 per cent.; lymphocytes, 23 per cent.; transitionals, 2 cent., and cosinophiles, 1 per cent. A discharge from the ear showed the *B. pyocyaneus*. The feces showed some blood microscopically. The child was restless, irritable, and cried constantly, though the temperature and pulse were only slightly elevated. A diagnosis of Henoch's purpura was made. The treatment consisted in the subcutaneous injection of 20 c.c. of the mother's blood at the time of admission. Blood transfusion was suggested, and the child's brother acted as the donor. The hemolysis and agglutination tests were negative. A transfusion was done by the Lindeman method on April 18, between 250 and 300 c.c. of blood being given. The tendency to bleed ceased abruptly and up to the present time had shown no tendency to recur.

Case II.—This was a case of mild secondary anemia following injury occurring in a male child 18 months of age, who gave a history of having had a supposed meningitis, double otitis media, and bronchopneumonia. On August 15 he fell down a flight of stone steps striking the left temporo-parietal region and producing a decided lump and contusion. He was rendered unconscious but had no paralysis. Two days later he seemed drowsy, lost his appetite, and vomited occasionally. For three weeks he lay in a semicomatose condition; then gradually his mental condition cleared. The child was admitted to the Post-Graduate Hospital on September 30, 1914, in a very relaxed and emaciated condition, his weight at this time being 16 pounds 8 ounces. The child had a double otitis media, moist rales over both lungs, an irregular temperature albumen in the urine, but no pyelitis. The Widal reaction was negative. The blood count showed red cells 3,000,000; hemoglobin, 54 per cent.; leucocytes, 38,000; with 78 per cent. polymorphonuclears and 22 per cent. lymphocytes. The boy was transfused on October 22, 1914, the mother acting as the donor. The amount given was 350 c.c. Improvement commenced with the operation and progress toward recovery had been uninterrupted. After transfusion the blood count showed red cells 4,456,000, hemoglobin, 68 per cent., and the leucocytes had dropped to 12,300.

Case III.—This was a case of Henoch's purpura in a girl, 11 years of age, who was admitted to the Post-Graduate Hospital on May 21, 1914. Her personal and family history were negative, except that she had had measles and scarlet fever. Two months previous to her admission to the hospital she became ill with diarrhea and abdominal cramps. The latter symptom increased in severity and was most marked in the lower right quadrant. Appendicitis or nephrolithiasis was suspected. A rash appeared on the legs, knees, hands, and elbows. Blood was passed *per rectum*. The temperature was 102° F. and pulse 140. At this time any slight trauma would be followed by ecchymosis. A little later the child had three convulsions evidently of uremic origin and the urine showed blood. There was edema of the feet, legs, face, abdomen, and back which progressed until there was general anasarca. This edema had gradually disappeared until at the time of admission it was scarcely noticeable. Aside from the poorly nourished anemic condition physical examination revealed nothing abnormal except that the post cervical chain of glands, particularly on the left side, were slightly enlarged. Some of the symptoms of rachitis were present. There were purpuric spots on both knees and also large ecchymoses on the left external malleolus. The left epitrochlear gland was palpable and the inguinal glands were palpable and slightly enlarged. There was blood in the stools both microscopically and chemically. Blood examination showed red blood cells 3,168,000; hemoglobin, 35 per cent.; white cells, 18,000; with 77 per cent. polymorphonuclears and 23 per cent. lymphocytes. The child was given a blood transfusion of 270 c.c., the father being the donor, and the preliminary tests having been satisfactory. Immediately after the transfusion the child looked and felt better. She was dismissed from the hospital on June 1st, at which time her blood count showed red cells, 4,256,000; hemoglobin, 65 per cent.; leucocytes, 11,700; with 60 per cent. polymorphonuclears and 40 per cent. lymphocytes.

Case IV.—This was a case of chronic sepis following pneumonia and empyema. This patient was born on October 23, 1913, and had been well until the present illness. He had had pneumonia during the latter part of July and was brought to the hospital three weeks later with an empyema on the right side. He was operated upon by Dr. Vincent at which time his weight was 20 pounds 12 ounces. He ran a very high temperature and gradually lost weight and

strength and refused food. This was followed by diarrhea which further weakened the boy. The prognosis was considered hopeless but as a last resort transfusion was suggested. A blood transfusion of 235 c.c. of blood, the mother being the donor, was given. The temperature dropped immediately and remained down. The child's appetite was ravenous. The blood count before transfusion was: red blood cells, 3,847,000 and hemoglobin, 40 per cent.; today the red blood cells numbered 4,220,000 and hemoglobin was 77 per cent.

Dr. ALFRED M. HESS said that in the treatment of the conditions under discussion by blood transfusion, etc., a sharp distinction should be made between immediate results and permanent ones. In cases in which there was a possibility of this treatment replacing blood, stopping hemorrhage, or combating sepsis it should be used. It should be remembered that in purpura hemorrhagica the attacks were sometimes very infrequent; in one case coming under his observation there was a recurrence of the condition after ten years; in other instances it recurred at longer or shorter intervals, so that whether transfusion was of permanent value in purpura hemorrhagica remained to be seen. In one case of hemophilia in which he had seen this treatment used it did no good, the coagulation time of the blood continued to be as long as before the transfusion. In another instance transfusion had been performed three or four times and each time the hemorrhage recurred; this was a case of purpura hemorrhagica. Whether transfusion was of more than immediate value was still problematical. Dr. Hess said he had also used another method, that of defibrinating the patient's own blood and reinjecting it. This stopped the hemorrhage. In one instance this procedure had been carried out three times and it stopped the hemorrhage for a week or ten days after the serum was injected. This method had the advantage of being highly practicable; no hemolytic tests were required, no difficult technique, no donor. The injections of autogenous blood should be tried in cases of purpura with hemorrhage.

Dr. WILLIAM SHANNON stated that he had recently seen a case of hemoptysis and that Dr. Hess had also seen the case. The child had been bleeding for a week and the family history showed that hemophylia was a family characteristic. There was a history of rheumatic purpura and of purpura hemorrhagica, a combination of the two conditions. It seemed that in this case transfusion might be of benefit.

The Extent of Tuberculous Infection among the Children of New York Tenements as Evidenced by the Application of the Cutaneous Tuberculin Reaction.—Dr. MAURICE FISHBERG presented this communication. He recalled that a year ago he had reported as to the tuberculin test in 692 children of tuberculous parentage among which the reaction was found positive in 67 per cent. of the cases, and at the age of fourteen the proportion of "reactors" was even as high as 83.79 per cent. The report now presented was on the application of the von Pirquet test to 589 children of non-tuberculous parentage. They were all of poor economic and social status, depending on charity wholly or in part for subsistence. On the whole they were considered healthy by their parents. They lived in the tenement district of New York City. He found that 52.72 per cent. showed positive reactions to the cutaneous tuberculin test. Among the children under one year of age only 10 per cent. reacted; among those between one and two years of age 33.38 per cent.; between three and four years of age 41.25; between five and six years of age, 50 per cent.; between seven and ten, 64.74 per cent.; between eleven and fourteen, 69.4 per cent., and at fourteen years, 75 per cent. These figures, though apparently startling, were in agreement with conditions found in various European cities.

Dr. GODFREY R. PISEK said he would like to ask Dr. Fishberg whether in the families ruled out as not having tuberculosis there were any boarders or lodgers? He wanted to know whether the converse of his statement was not the more important; whether if there was no reaction there was no possibility of the child having tuberculosis (excluding terminal cases of course). If this were true the reaction would still be of distinct value.

Dr. ABRAHAM HYMANSON called attention to an article which he had published in the Archives of Pediatrics, August, 1912, on "Tuberculosis in Young Children," in which he had stated that during the years of 1909 and 1910 he had applied the Moro and von Pirquet test on 68 infants from two days to two weeks of age, the mothers being apparently free from tuberculosis, and none of these children showed any trace of the disease. In another series of 18 cases he had applied both of these tests, in both the infants and the mothers. Four of the mothers showed a positive reaction and three of these showed physical signs of the disease. The infants invariably showed a negative reaction. He had looked for enlarged glands in 86 infants but found none, with the exception of one infant, all of whose glands were enlarged. There was no history of syphilis in this case. Dr. O. Bondy had applied the cutaneous tuberculin reaction in 350 cases of new born infants between the second and fourth days after delivery and found the test negative in all, although it was positive in 71 of the mothers. Drs. Paten and Grietert had applied the von Pirquet test in 53 children less than two weeks old and none of them showed a trace of reaction. Other observers had made similar tests and the fact seemed to be established that with very few exceptions infants were born free from tuberculosis, but that they contracted it during infancy or childhood.

Dr. LEON T. LEWALD said that he had made radiographic examinations of the lungs of many children who had given a positive tuberculin reaction and on no occasion had he found lung lesion, except in miliary tuberculosis; even when the children showed positive signs of the disease the lung was not infiltrated, but the process was located somewhere else in the body, in the bones, joints, on lymph nodes, but not in the lungs.

Dr. FISHBERG, in closing the discussion, said that Dr. Pisek's question was a very proper one in view of the ubiquitousness of tuberculosis. In an investigation of an isolated mountainous district in Scandinavia with a population of one hundred among whom there had not been a death from tuberculosis for ten or fifteen years, Overland found that 75 per cent. of the population gave positive reactions to the tuberculin test. After investigation it was found that the village teacher was a consumptive and responsible for this high percentage of infection with tuberculosis. Direct contact was not necessary to transmit the disease. This was evident from the fact that a cow which reacted positively to tuberculin, placed with a herd every one of which reacted negatively, resulted after a few months in a considerable number of positive reactions among that herd, though there might be no well developed instance of tuberculosis. As to a negative reaction, this often meant nothing whatever. Where the reaction was positive and the disease was present it need not necessarily be in the lung, but might be in a joint, in glands, or other organs since it was the organism that responded to the tuberculin test.

Experience with the Diphtheria Toxin Skin Reaction of Schick.—Dr. WILLIAM H. PARK made this presentation. He said that he had brought with him two students who had submitted themselves to the Schick test and showed reactions. The Schick reaction was just the reverse of all other tests in that a negative reaction meant immunization and a positive one meant susceptibility to the disease. The Schick reaction was due to the direct toxic action of the toxin of diphtheria. The negative reaction meant that the toxin was neutralized and a positive reaction meant that the patient did not have sufficient antitoxin in the blood to neutralize the toxin introduced. There was also a pseudo reaction which was anaphylactic in type and was in reality due to the endotoxins. It gave the impression of a much more decided reaction that the true reaction. In the pseudo reaction there was slight hyperemia and infiltration at the site of the injection. To demonstrate the difference between the true and the pseudo reactions Dr. Park exhibited two guinea pigs. The one had been subjected to a double Schick test; that was, at one site an injection of diphtheria toxin alone had been given, while at a second site a similar dose of toxin together with sufficient antitoxin to neutralize it had been administered. At the site of the first injection there was an induration, while at the site of the second injection the toxin had been completely neutralized and there was no lesion. A second pig had been inoculated with a non-virulent culture and showed the pseudo reaction which was larger than the true reaction and mean that the pig was immune. The pseudo reaction came quickly and went quickly, while the true reaction lasted for a week or two before disappearing. In applying the Schick test the dosage used was about one-fiftieth of the fatal dose, though it might be as low as one-sixtieth or as high as one-thirtieth; with a larger dose there was danger of necrosis. If there was not an active

antitoxin present and the reaction was doubtful the subject was put down as non-immune. Dr. Park exhibited charts showing the result of the Schick test in children from the time of birth to the fifteenth year and in adults when the toxin was administered subcutaneously, intramuscularly, and intravenously. In children between the ages of five and fifteen years 50 per cent. showed a positive reaction; in those between the ages of four and six years about half were immune to diphtheria and half were non-immune. In younger children 60 per cent. were immune, while among adults 70 per cent. were immune. In certain children "once immune always immune" seemed to hold good, while in others who had had the disease the test might be used to determine the limit of immunity. At the Willard Parker Hospital they were immunizing all the children admitted to the scarlet fever wards, but only those that showed a positive Schick reaction. A child that gave a negative Schick test was positively safe among diphtheria carriers. Several other applications of the reaction could be made. When the toxin was given intravenously the reaction was increased. If a case was supposed clinically to be diphtheria and one got a negative Schick reaction and a positive diphtheria culture one might conclude that the patient was only a carrier and did not have true diphtheria. About one-third of the cases of diphtheria developed antitoxin while two-thirds did not. When one positive Schick reaction was found in a family it was likely that all the members of that family would have a positive test. Immunity to diphtheria seemed to be acquired; adults and young infants gave a large proportion of negative reactions, but during infancy and childhood the immunity dropped off and then the antitoxin began to be produced again as the children grew older; they did not know the explanation of this. Some individuals produced a large amount of antitoxin; as much as fifteen units had been observed, but whey it should be produced beyond the apparent need was beyond comprehension.

Types of Pneumococcus Bacilli and Their Characteristics.—Dr. RUFUS I. COLE presented this communication. He stated that a study of the races of pneumococci isolated from cases of pneumonia revealed four types of organisms. They had named those groups in which a considerable number of organisms were found to have common immunological characters Types I and II. The Pneumococcus mucosus (Streptococcus mucosus of Schottmüller) had been called Type III, and the group of organisms having no common immunological characters they had called Type IV, or preferably Group IV. For the past two years all organisms isolated from cases of pneumonia had been studied as to their immunological reactions. A study had now been made of the organisms obtained from 150 cases of pneumonia. The result of this study showed the relative frequency of the various types to be as follows: Of Type I there were 57 cases, 38 per cent.; Type II, 44 cases, or 30 per cent.; Type III, 17 cases, or 11 per cent.; Type IV, 32 cases, or 21 per cent. Observations along the same lines had been made by Walker at the Peter Bent Brigham Hospital, Boston, and the Pennsylvania Hospital, Philadelphia, by Dr. Paul Lewis; altogether about 300 cases were studied. The results of these studies coincided very closely with those that had been obtained at the Rockefeller Institute. It seemed that they might safely conclude that there was one type of severe infection due to pneumococci of Type III, in which the mortality was high; a second group of cases of lesser severity, due to organisms of Type II; a third group of cases, only slightly less severe, due to pneumococci of Type I, and finally, a large group due to the non-fixed type of organisms, Type IV, in which the symptoms were milder, and which usually ended in recovery. From the standpoint of prognosis alone, therefore, the determination of the type of infection in the individual case was of considerable importance. They had been studying the toxic action of the pneumococcus with the idea of getting a serum which would be efficacious in pneumonia. It had been impossible up to the present time to get any direct proof that the effects of the pneumococcal growth in the body were due to the elaboration of a poisonous substance. The speaker, after discussing the theories in regard to endotoxins and ferments in nontoxin producing bacteria, described his experiments with the filtrates of cultures, which gave no specific effect; with solutions of bacterial cells, (*a*) in salt solution, (*b*) in cholate solutions, and (*c*) by freezing and grinding. They found that in all three instances the result was acute death of the guinea pigs and hemolysis of the red blood corpuscles. Broth cultures of the pneumococci were found to transform oxyhemoglobin into methemoglobin. They then further studied this change of oxyhemoglobin into methemoglobin, using broth cultures with living pneumonia, broth cultures with dead pneumococci, solutions of bacterial cells, filtrates of bouillon cultures, and washed bacteria in salt solution, in the presence of blood and a small amount of dextrose. They also studied the effect of oxygen in the transformation of oxyhemoglobin into methemoglobin and as a result of their observations concluded that for the formation of methemoglobin by pneumococci the presence of living bacteria were necessary, and since the presence of minute amounts of nutritive material was also necessary, it was probable that these bacteria must be actively carrying on nutritive functions, probably undergoing multiplication. Such substances must be present in the fluid immediately surrounding the bacteria. If the corpuscles and bacteria were separated by any limiting membrane, as by a dialyzing membrane, or even a thin layer of oil, no reaction occurred. These together with other observations made it seem possible that the formation of methemoglobin depended upon some active substance given off by the bacteria, and this substance became inactive as soon as it diffused through the surrounding medium. The suggestion then occurred that the substance given off by the bacteria was in the nature of a ferment, being rapidly weakened or destroyed by diffusion. From their observations of the transformation of oxyhemoglobin into methemoglobin with reference to the effect of oxygen it seemed not unlikely that the formation of methemoglobin occurred in the neighborhood of pneumococci because of a modification of oxidation and reduction processes in the medium immediately surrounding the bacterial cells. This change must be a specific one in the case of the pneumococci, otherwise all living organisms would cause this reaction, which was not the case. This theory seemed applicable to conditions in pneumonia provided one assumed a widespread distribution of the bacteria throughout the body, but after all they had to admit that the exact nature of the intoxication in pneumonia was still obscure. In studying the action of pneumococcus immune serum they had succeeded in immunizing sheep, but when they had undertaken to transfer this immunity passively to guinea pigs the results were very questionable and they must believe that it was very doubtful whether any neutralization of the toxic substance could be obtained in this way. The experimental studies did not indicate that an immune serum obtained by the injection of toxin possessed any high degree of antitoxic power. Their studies had shown why immune serums such as had been used in pneumonia would not be likely to show any beneficial results. In the first place, a pneumococcus immune serum was effective only against the type of organism used in the process of immunization. If, for instance, immunization was carried out with Type I organisms it might be expected that it would have no effect on any infection due to one of the other types of pneumococci. If the immunization was carried out with one of the organisms of Type IV it could have no effect on any infection except that due to the same race. They had lately examined an antipneumococcus serum on the market which was said to be polyvalent; their experiments had shown that it had absolutely no protective power against organisms of Type I or Type II, or, in fact, against any of the organisms against which they had tested it. Its use in the treatment of penumonia undoubtedly did more harm than good. In order to render an antipneumococcus serum theoretically useful in any type of pneumonia, it would be necessary, first, to produce a serum with high protective power against the type of organism concerned; second, to have a satisfactory method of standardizing such a serum, and last, to have a method of quickly determining the type of organism for each individual case. These conditions had been satisfactorily met as far as Types I and II were concerned. As for Type III it had been absolutely impossible to produce a serum having any protective power whatever. The use of immune serum in infections of this type was entirely without justification. Fortunately, infections of this type were relatively infrequent. Active immune serum might be produced to each of the organisms which had been placed in Group IV, but the serum in each case was effective in protection only against the individual race used for immunization. Therefore, such a serum could not be employed with any hope of success. Infections of this type were relatively mild. The cases belonging

to Types I and II constituted the largest number of cases of this disease seen in New York and probably in this country. They had found a method by which it was possible to standardize immune serum with a fair degree of accuracy. They had also worked out a method by which they could determine the type of organism in the individual case in a comparatively short time. As soon as a patient was admitted to the hospital, a portion of sputum coughed directly from the lung was obtained if possible, and, after washing, this was made into an emulsion in sterile salt solution or bouillon, and injected into the peritoneal cavity of the mouse. Cultures were made from the blood of the patient, or in case a satisfactory specimen of sputum could not be obtained directly from the involved portion of the lung by the insertion of a sterile needle. Five hours after the injection an emulsion was made from the washings of the peritoneal cavity of the mouse and the agglutinability tested against an equal part of immune serum of Type I and Type II. When agglutination occured it was usually within half an hour. On theoretical grounds it was important that the serum should be administered early, before the degree of infection was too great. When the type of organism had been determined and found suitable for serum treatment an intravenous injection of the appropriate immune serum of 80 or 90 c.c. was administered and a second dose given at the end of twelve hours. These doses were repeated the following day and on successive days as the condition of the patient indicated. This treatment had thus far been carried out in only a small series of cases, too small to permit the drawing of any definite conclusions, but the results had been extremely encouraging in pneumonia due to organisms of Type I. When the disease was due to organisms of Type II the results had not been so satisfactory owing to differences in different serums, the fact that it was more difficult to produce a serum of high protective power, and the fact that the maximum infective dose which might be protected against by immune serum of Type II was smaller than that which might be protected against in Type I. It was apparent that in the actively immunized animal there was some immunity factor which could not be transferred with the immune serum. In the future study of this subject it seemed most important to learn more of this second factor concerned in immunity and to attempt to find methods for transferring it from one animal to another.

Dr. William H. Park asked Dr. Cole whether using Type I serum might not do some good; would it not help perhaps about one-half of the cases? Of course it would do no good in a case of pneumonia due to Type III organisms. They were often called up over the 'phone and asked in regard to the administration of vaccines in pneumonia and they had been telling inquirers not to use the serums. As to the prognosis, if one learned twenty-four hours after seeing a case of pneumonia to which type it belonged, should he be guided in prognosis by the group to which the case belonged or by the clinical appearance of the patient? For instance, if the patient had a light attack and one found that he had the bacilli belonging to the third group, should a serious prognosis be based on laboratory findings?

Dr. Cole replied that if one were sure he had a certain type of bacilli the thing to do was to administer the appropriate serum, but in their animal experiments they had found that to be effective they had to give large amounts of serum. One might do harm with such large amounts of serum and their administration would scarcely be practical. It was not worth while trying a serum, unless one knew with which type of pneumococcus he was dealing and was sure that he was doing some good, until they had had further experience with the various types. The determination of the type was of great value in prognosis. Just yesterday Dr. Cole said he had seen a man, 65 years of age, who seemed to be in a very serious condition. The organism was found to belong to Group IV and he felt more cheerful as to the outcome of the case. In reply to the question as to how they determined the various groups, Dr. Cole said that all pneumococci were determined by the agglutination and protection tests. Any one of the types would not react against any of the other types. They made the tests by the simple method of injecting animals as he had described. In reply to the question as to whether a mixture of the sera of two groups had been found practical, Dr. Cole said they had used an unimmunized horse and titered to the type used to produce the immunity; as yet Type II showed a very low titer. If one could determine the type it was better to give the serum for that type alone. In reply to the question as to whether he thought pneumonia was a direct infection of the lung or a hematogenous infection, Dr. Cole said that from his experience he believed that it was a direct infection of the lung. Their experiments led them to believe that more than contact played a rôle in infection, that there was an autogenous factor.

Dr. Park said that Group IV as he understood it was not a group in the proper sense of the word; this group might embrace a large number of varieties of pneumococcus bacilli, and there might be some semi-saphrophytic ones. This was an important question with him as it had some relation to the present discussion in regard to subway crowding.

Dr. Cole said that in reply to the question as to whether there was any deterioration of the sera with time, he could not say as they had not kept their sera long enough as yet. Six months was the longest time they had kept any; it had not seemed to deteriorate in that time but it might do so later. Someone had asked as to the possibility of the transformation of one type of bacilli into another; in their experience they had never seen one type transformed into another. Type I had passed through one hundred and twenty-five animals and remained Type I always. Transformation might be possible, but they had never observed it. They had examined the types during the various stages of the disease and during convalescence and the agglutination tests always showed the same organism. What Dr. Park had said of Group IV was true; there might be one hundred and fifty varieties, but each was an individual type and absolutely distinct. They seemed to have found two types of organisms in South Africa that had not been observed here. In reply to the question whether a patient might have an infection consisting of organisms of more than one type, Dr. Cole said that he had never found Type I and Type II at the same time. If Type I and Type IV were both present, Type I came out and Type IV did not. Type I was more virulent and suppressed Type IV. One never got an "even up" mixture. In reply to Dr. Kerleys's question as to why the mortality was lower in children than in adults, he had made no observations along that line and had no theories to offer.

Pathological Society of Philadelphia.

At a stated meeting held February 1, Dr. S. W. Sappington presented (1) "Specimens of Duodenal Ulcer"; (2) "Myoma of the Stomach"; (3) "Polyp of the Stomach."

Drs. Moses Behrend and I. Valentine Levi presented a specimen from "A Case of Lymphangioma Congenitum Cysticum Multiplex." There had been no difficulty in the birth of the child, which presented a tumor on one side of the neck. The possibility of removal surgically was considered, but had to be abandoned. The conditions discovered after death showed that operation could not have succeeded on account of the deep and intricate ramifications of the growth about the great vessels and the nerves of the neck.

Dr. Moses Behrend presented a "Specimen from a Case of Recurrent Extrauterine Pregnancy." About a year after operation for intraabdominal hemorrhage due to rupture of an intrauterine pregnancy, the patient, again pregnant, presented symptoms of irregular bleeding from the vagina, and for the relief of which operation was undertaken. On this occasion the bleeding was found to come from a partially ruptured oviduct within which was still contained a fetus at an early stage of development.

Dr. Behrend presented also a specimen from "A Case of Traumatic Meningitis (Forceps Operation) in a Newborn Infant." Delivery was attended with considerable difficulty, and application of forceps was required. Some injury was inflicted upon the head and neck of the infant, which weighed ten pounds at birth. For a while no sequel was noted, but after the lapse of several days rigidity, opisthotonos and muscular twitchings developed together with elevation of temperature. Also a gland in the neck broke down and discharged. In a few days more death ensued, and post-mortem examination disclosed a fairly extensive meningitis of convexity and base, without evidence of hemorrhage or traumatism. From the exudate a diplococcus believed to be the pneumococcus was isolated.

Dr. Martin E. Rehfuss presented a communication entitled "Further Studies on Experimental Gastric

Ulcer." He succeeded in demonstrating that in guinea-pigs erosion or ulceration of the stomach could be induced by subcutaneous injections of various toxic substances, such as venom of heloderma, and different alkaloids and a number of microorganisms. The lesions developed rapidly, in the course of several hours, and soon resulted in perforation.

Dr. ALFRED GORDON presented a preliminary communication describing "A New Test on Blood-serum and Cerebrospinal Fluid in Cases of Syphilitic Involvement of the Nervous System." It was found that when to clear blood-serum from apparently healthy or at least non-syphilitic persons there was added a drop or two of a 1 per cent. solution of mercuric chlorid in water slight transitory turbidity might develop, but when serum from a syphilitic was treated in the same way a coagulum formed at the surface, and which in the course of twelve or twenty-four hours became denser and sank to the bottom. On the other hand when cerebrospinal fluid obtained by lumbar puncture was treated in a corresponding manner turbidity resulted when the fluid was obtained from a syphilitic and no change took place when the individual was non-syphilitic. Comparisons with the Wassermann reaction showed that there was a close correspondence in the results of the two sets of tests. Observations were made on a variety of forms of syphilitic infection, at varying stages and involving the nervous system and other structures as well.

Drs. JOHN A. KOLMER and E. L. MOSHAGE presented a communication entitled "The Schick Reaction as a Measure of Immunity in Diphtheria." The test consists in the introduction of a minimal amount of diphtheria-toxin into the skin, and it has been found that individuals who possess as little as one-thirtieth of a unit of antitoxin within their system yield no reaction, while those deficient in immunizing bodies yield a more or less well-marked reaction at the site of inoculation, marked by redness and induration. The test is useful in rendering unnecessary prophylactic the employment of antitoxin in the case of individuals exposed to infection or otherwise suspicious and who do not yield the Schick reaction. In a small epidemic of diphtheria in a hospital of a large number of those tested and found negative only one nurse who took part in the care of some of the actual cases, developed a mild attack of diphtheria. By means of the test it was possible also to demonstrate the brief duration of the artificial immunity induced by an attack of diphtheria or by injection of antitoxin or in both of these ways. It was found that within less than a montht such individuals responded to the Schick test in much the same proportions as did individuals under ordinary circumstances. Also it was found that a large proportion of children do not yield the reaction during the first year of life.

Erythema Due to Carbon Monoxide Poisoning.—I. J. Davies states that acute erythema occurred in nine of eighteen survivors rescued after an exposure to noxious fumes in a mine for twenty hours. The lesions most commonly involved the buttock and generally the skin over the tuberosity of the ischium was affected. In other situations the skin over bony prominences was most commonly affected. The patches were of irregular shape and attended by considerable swelling of the part, and of a brilliant cherry-red color which faded on pressure. The patients complained of considerable pain in the regions affected which were very tender. Absolute anesthesia was a marked feature throughout, and was still evident in some of the cases after a period of six months. These facts strongly suggested that the cutaneous lesions of carbon monoxide poisoning are of the nature of an angioneurosis, while pressure merely determined the situation of the lesions and was not the causal factor. Erythematous lesions similar to those described were found on several of the bodies brought up within a few days of the disaster. The remaining bodies were not brought out of the mine for several weeks, while some could not be removed from under falls of roof for several months. Thus systematic examination was impossible owing to decomposition, and the necessity for prompt removal after identification and certification of the cause of death. The facts described go far to support the view expressed by the writer that the cutaneous lesions were not primarily pressure phenomena, but true manifestations of after-damp poisoning.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

Cosmetic Creams.—Max Joseph states that these dissolve sebaceous material and the fatty acids of the sweat, and by their saponifying action form an excellent vehicle for the suspension of dirt. They also impart to the skin a gloss, and make a dry, rough skin soft and pliant. The following is the formula of violet cream:

℞ White wax,
Spermaceti, āā 6 grams.
Oil of sweet almonds, 30 grams.
Rose water, 45 grams.
Oil of violets, 4 grams.
—"A Short Handbook of Cosmetics."

Treatment of Ophthalmic Migraine.—S. E. Jelliffe recommends the following for the evanescent abortive attacks:

℞ Antipyrine, ʒj.
Citrated caffeine, gr. xv.
Elixir of sodium bromide, ad ʒij.
M. Sig.: ʒj every fifteen minutes for three doses.

If the attack is in the chilly, creepy stage, with beginning scotoma, and before the headache begins, the following may be given:

℞ Antipyrine, gr. xv.
Nitroglycerin, gr. 1/10.
Elixir of pepsin, ad ʒj.
M. Sig.: ʒj every five minutes for three doses.

Acetylsalicylic acid may be given in doses of 5 grains every ten minutes with a little coffee.—"Modern Treatment of Nervous and Mental Diseases."

Chrysarobin in Psoriasis.—G. T. Jackson finds that the best method of using this drug is a modification of the combination recommended by Dreuw, as follows:

℞ Salicylic acid, 10 grams.
Chrysarobin,
Birch tar, āā 20 grams.
Lanolin,
Goose fat, āā 25 grams.

The chrysarobin reaction is usually mild.—"Diseases of the Skin."

Treatment of Loss of Hair.—R. Sabouraud recommends the use of pilocarpine, especially in the loss of hair so frequently seen in women. His formula is:

℞ Alcohol, 90 per cent., 250 grams.
Spirit of lavender.
Spirit of ether, āā 25 grams.
Pilocarpine muriate, 0.25 gram.
Water, q. s.
Ammonia water, 4 grams.
M. Sig.: For external use.

For Pruritus Ani.—P. Lockhart-Mummery has found the following an effective application:

℞ Bismuth subnitrate, ʒ ij.
Tincture of opium, ʒ j.
Cocaine hydrochloride, gr. xx.
Phenol, ♏v.
Dilute hydrochloric acid, ♏xx.
Lanolin, ʒ ij.
—"Diseases of the Rectum."

Glyceryl Trinitrate in Hemicrania.—M. T. Schnirer states that Mendel recommends the following:

℞ Glyceryl trinitrate, 0.1 gram.
Alcohol,
Phosphoric acid, āā, 10 grams.
M. Sig.: Two drops twice a day.
—"Taschenbuch der Therapie."

FURTHER REMARKS ON SYPHILIS OF THE STOMACH.

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

QUITE a number of years ago I wrote a paper[1] on syphilis of the stomach. In this article the more important literature on this subject may be found. Later on I wrote two additional papers[2,3] on syphilitic tumors of the stomach.

Since then the following clinicians have broached the question of syphilis of the stomach.

Siegheim[4] related a case of syphilitic tumor of the stomach, which he observed, and whose symptoms resembled those of carcinoma.

Myer[5] described two cases of gastric tumors, due to syphilis. In one patient, who was operated upon, an inoperable tumor was found, and in the other a tumor the size of half a fist was found in the epigastrium. Thorough antisyphilitic treatment caused the tumors to disappear in both cases.

Leven[6] reports two cases of syphilitic pyloric stenosis, which were entirely cured by antisyphilitic treatment. In one of these patients the Wassermann reaction was negative. Leven makes it a rule never to turn over a case to the surgeon before antiluetic treatment has been tried; in this way we may recognize the syphilitic nature of the trouble.

Hausmann[7] usually found anacidity in syphilitic gumma of the stomach. The combination of symptoms of ulcer with anacidity speaks for syphilitic ulcer.

In another somewhat later article Hausmann[8] described three cases of callous or penetrating syphilitic ulcers of the stomach, which he had observed himself and believed that they were not at all unique, and that similar cases are seen by surgeons, but are not interpreted correctly by them. The ulcers are accompanied by anacidity.

For the microscopical examination of gummatous tissues the usual methods of staining with hematoxylin eosin and Van Gieson are frequently insufficient. When we suspect syphilis it is necessary to study the changes of the vessels by means of a stain for elastic tissue and we must employ a stain with polychrome methlyene blue or pyronin methyl green.

Comite[9] described a case of syphilitic tumor of the stomach. It was the size of a pigeon's egg and felt hard, resembling a cancer in every respect.

Copelli[10] reported several cases of syphilis of the stomach, observed by himself, and believes that they are not so rare. He is of the opinion that in every case of severe affection of the stomach, that is not amenable to treatment, the possibility of syphilis must be considered.

The subject of gastric syphilis, although of great practical importance, is but scantily represented in the latest medical literature. For this reason I deem it of interest to publish my new experiences regarding this question. I shall, however, limit myself in citing some of my new cases serving as paradigmata, as a full description of all would be too lengthy.

At first I would like to describe two new cases of syphilitic tumors of the stomach. They are very rare, but most important, for they at times resemble a malignant neoplasm in the minutest details.

CASE I.—Fred B. J., 46 years old, colored was admitted to the Post-Graduate Hospital, Nov. 19, 1913. Patient had always been well until a year ago, when he noticed distress at night four to five hours after supper, usually lasting for about one hour. At first this came on occassionally but since about three months (August, 1913) it has been constant. The symptoms are relieved by eating or taking alkalies. He has never vomited blood or passed blood in the stool. The pain is usually localized in the epigastrium and now comes on three to four hours after meals. He has lost thirty pounds in the last six months. His habits are good, he does not drink or smoke.

Present condition; heart and lungs negative; in the epigastric region midway between ensiform cartilage and navel a resistant mass of 1½ inch thickness can be distinctly felt; liver slightly large. Reflexes and urine normal.

Examination of stomach contents one hour after a test breakfast, on Nov. 22, 1913 (180 c.c. recovered), reveals absence of free HCl, total acidity = 8, lactic acid faintly present; no blood.

Wassermann reaction is strongly positive.

Examination of stomach contents, on Nov. 28, shows in 100 c.c. of contents absence of HCl; total acidity = 7; lactic acid absent; blood moderate reaction. Feces show no blood.

Thirty c.c. of a retention meal are recovered and give a strongly positive blood reaction. Nov. 30, neosalvarsan, eight grains are given intravenously. Dec. 9 and 12, mercury salicylate, one grain intramuscularly. Nov. 15, *x*-ray reports evidence of calloused pyloric ulcer. Nov. 21, partial defect at pars pylorica. Stomach vertical orthotonic type. No residue at end of six hours. (Figs. 1 and 2.)* Intestinal hypomotility present. Pylorus is at level of umbilicus in the median line, lesser curvature being to left of median line.

Diagnosis from the *x*-ray examination by Dr. I. S. Hirsch: Carcinoma pylori.

Nov. 22. The thread test shows no bile, no blood (the duodenal bucket did not pass the pylorus). Nov. 25. Findings with thread same as on Nov. 22. Dec. 12. Thread test shows bile stain, but no blood (the bucket has passed the pylorus).

Weight: Nov. 22, 116½ pounds; Dec. 3, 119½ pounds; Dec. 12, 122½ pounds.

March, 1914, patient is presented at my lecture. He has gained 30 pounds in weight and feels perfectly well. He eats everything without any discomfort. The physical examination of the abdomen fails to reveal anything abnormal.

CASE II.—Nov. 19, 1909. J. L., about 47 years old, was troubled with pains and vomiting for the last five to six months and had lost 40 pounds. Examination

*I am indebted to Dr. I. S. Hirsch, radiologist at the Post-Graduate Hospital, for the two beautifully executed *x*-ray photographs.

of the abdomen revealed a resistant mass, occupying the left hypochondrium and extending from the costal margin for about two and a half inches downward. The mass was uneven and hard. The gastric contents showed absence of HCl. and presence of lactic acid and blood. The family physician reported that a Wassermann reaction had proved to be negative. Based upon these findings the diagnosis of cancer of the stomach appeared to be positive and an operation was recommended with a view of either excising the growth or at least establishing a gastroenterostomy.

FIG. 1.—X-ray photograph of stomach of Fred B. J. after ingestion of a bismuth mixture. The greater curvature near pylorus shows a distinct defect in outline.

At the operation an inoperable tumor of the stomach was found. Even a gastroenterostomy was not feasible on account of the technical difficulties. The patient got over the effect of the operation, but continued to suffer as before. About one month after the operation he called on me for relief. On examination I found the same mass as described before. Notwithstanding that the Wassermann reaction was negative, I decided to give him iodides. The drug acted almost like a charm and soon afterwards he began to feel better. Later on a regular antispecific regimen was rigorously carried out and the patient entirely recovered and is still living and well. The tumor has entirely disappeared.

Syphilitic tumors of the pylorus are already somewhat more frequent than those of the stomach proper. I have seen quite a number of them, but will cite one as a good representative of this affection.

CASE III.—February, 1910. Mrs. F. has been complaining for three years of occasional attacks of severe pains, accompanied by vomiting of large quantities of food. For the last five months the vomiting has increased in severity; she has also lost considerably in flesh. Upon examination the stomach was found to be extremely dilated, extending almost to the symphysis and a small tumor the size of a large walnut could be distinctly palpated in the pyloric region. Her stomach in the fasting condition contained over a pint of stagnating food; HCl was present, total acidity increased. A régime of lavage and liquid food failed to bring on any marked improvement.

Her stomach even then contained quite a quantity of gastric juice mixed with food particles in the fasting condition. The vomiting and pains likewise persisted. She was given iodides tentatively. After a while she began to feel better, her stomach was empty in the fasting condition, and the tumor appeared to be somewhat smaller. Mercurial inunctions were now added to the iodides. The patient was treated 4 or 5 months upon this régime. Her diet was increased, she gained in weight, her stomach continued to be empty in the morning, and after a while no resistance could be felt in the pyloric region.

Syphilis of the central nervous system associated with a probable duodenal ulcer was encountered in the following case:

CASE IV.—October, 1913. Mr. de T., about 35 years old, is troubled with severe attacks of periodic vomiting for the last two years. These attacks appear quite suddenly, and are accompanied by severe headache, violent pains in the gastric region, and continuous vomiting, lasting from 3 to 5 days. At times the vomited matter contained blood. While these attacks at first used to come on about every 2 to 3 months, lately the period of free intervals has been shortened and now they appear almost every 2 or 3 weeks. Between the attacks patient feels better, but not well. He then complains of pains 2 or 3 hours after meals and obstinate constipation. He has lost within the last eight months about 40 pounds in weight.

The examination showed a dilated stomach and an extremely emaciated man. The liver was not enlarged, the knee reflexes were exaggerated, and slightly impaired coordination was present. The gastric contents showed hyperchlorhydria. The thread test established the fact that the pylorus was permeable and no blood stain was found. The stomach in the fasting condition was never empty, containing a great deal of gastric juice (between 60-100 c.c.). A retention meal given at night had left the stomach completely in the morning. Occult blood was found in the gastric contents. The *x*-ray examination confirmed the diagnosis of a dilated stomach and also showed some irregularity in the outline of the cap, but no definite diagnosis could be made.

Patient was given bismuth and atropine in large doses, but as he felt no improvement, it seemed as if an operation (gastroenterostomy) would have to be resorted to. I advised a Wassermann, which was positive, and with an antiluetic treatment the patient was relieved of all his symptoms.

Syphilitic ulcers of the stomach are quite frequent. I shall describe but one case.

CASE V.—October, 1912. Mrs. E., about 36 years old, was troubled for the last eighteen months with severe gastric pains and vomiting. Six months ago she threw up a large quantity of blood (about 1 or 2 quarts). Since then all the symptoms were aggravated and she continually grew worse. Upon her arrival at the hospital she stated that she had lost over 50 pounds in flesh. She could not retain anything given by mouth.

FIG. 2.—X-ray photograph of same patient 6 hours later. the stomach is empty; a shadow in the form of an irregular line remained in the place of the defect, indicating hardened tissue groove to which the bismuth sticks.

The examination showed a dilated stomach, extending almost to the symphysis. A test breakfast examination revealed the presence of HCl in normal amount and occult blood. The duodenal bucket showed that the pylorus was permeable and the thread was blood-stained between 42 and 52 cm., indicating ulcerations within the stomach. A Wassermann reaction proved strongly positive. Patient was put on duodenal alimentation and was given antiluetic treatment besides. She rapidly improved and within six weeks had almost regained her former health.

Inasmuch as any recognized mode of treatment that is usually considered efficacious in gastric ulcer had had no effect whatever upon her, and the fact that she recovered quickly after antisyphilitic treatment, supplemented by an ulcer cure, make it fair to assume that the ulcer was due to a specific syphilitic lesion.

Organic lesions of the stomach are frequently found in syphilitic individuals. At first we are prone to ascribe the gastric lesion to a luetic process. After a while, however, we become convinced that the affection of the stomach is independent of the coexisting syphilis.

As a good instance of this kind, the following case may be briefly outlined:

Case VI.—Case of syphilis and cancer combined in one patient. May 24, 1914. Wm. W., 54 years old, watchman, had never had any illness until six years ago, when he became short of breath, which has continued. He could not walk half a block without stopping for breath. Six months ago the shortness of breath increased and he lost 35 pounds. He slept poorly and whenever he took alcohol he vomited; his appetite was poor; bowels were regular. Formerly he was a heavy drinker, smoked 6 or 7 cigars daily, denies syphilis, but acknowledges having had a soft chancre. He went to a hospital for his troubles, but did not improve.

I first saw him at my office in April, 1914, and found upon examination a dilated heart and large liver with induration; besides this a distinct resistant mass in the epigastrium, extending to the left of the mammillary line and appearing to be connected with the lesser curvature of the stomach. A diagnosis of carcinoma had been made at the hospital which I had to corroborate according to the clinical findings. The patient, however, had been so weak at that time that an operation could not be considered. Having the possibility of syphilis in mind, I put him on an antiluetic treatment. This régime was followed by marked improvement for 3 or 4 months, during which time he also gained in weight and strength and his heart action improved.

While the liver diminished in size and the general condition was better, the resistant mass in the stomach remained unchanged. Ascribing the improvement in his general condition and in the state of his heart and liver to a syphilitic process, while that of the stomach to malignant disease (cancer), I now advised patient to be operated, which was done in a New York hospital. The tumor could not be resected. When I later saw patient I found the resistant mass somewhat larger in size, but there was no reappearance of the growth in the liver.

The following is a case in which the diagnosis of syphilitic or cancerous tumor of the stomach is still not definitely decided:

Case VII.—November 15, 1914. K. M., 44 years old, began to be troubled with distress 3 or 4 or 5 or 6 hours after meals, since February, 1913. At times, however, patient felt perfectly well, when the distress usually reappeared. The appetite was good and bowels moved daily. For the last three months patient felt worse, suffering from the same distress in a severer degree and waking up about one o'clock at night with pain in the stomach. Patient lost slightly in weight and felt weak.

Present condition, October 20, 1914: In the epigastrium, about one inch below the ensiform process and from here to the left a distinct resistance can be felt. The size of this mass is about two and a half inches in length and three-quarters inch in thickness; it lies horizontally toward and beneath the left costal arch. It is movable and goes up and down with deep inspirations. The stomach extends to one finger below the navel. The gastric contents, one hour after Ewald's test breakfast, reveal absence of free HCl, presence of rennet ferment, and fresh blood, macroscopically visible.

The blood showed slight anemia, but no leucocytosis. Wassermann reaction is two + +. Abderhalden reaction for cancer proved to be negative. Patient, however, is not conscious of ever having been infected by syphilis. The *x*-ray examination of the stomach failed to show the presence of the tumor.

In view of the given data it was fair to assume that the mass which could be distinctly palpated was due to gummata. Patient was therefore given an intravenous salvarsan injection on November 25, and treated by a vigorous antiluetic régime. On December 15 the mass had increased considerably in size and it was then as large as a fist. It had an uneven surface and was quite hard. Patient complained of the same symptoms as before; he could not lie comfortably and experienced pains at night and also at times during the day late after meals. The examination of the gastric contents one hour after Ewald test meal showed absence of HCl, presence of blood, no lactic acid, rennet ferment present. The duodenal bucket test showed a permeable pylorus and a slight blood stain on the thread. The diagnosis at that moment appeared to be that of cancer of the stomach, notwithstanding the positive Wassermann and the negative Abderhalden reaction.

On Dec. 28, or two weeks later, after having taken all this time the red biniodide of mercury and potassium iodide, the patient was reexamined. He then looked much better, had very little if any gastric pain, had not lost any weight. Palpation revealed very little tenderness over the epigastrium, and the resistant mass was less than half its former size (smaller than half a fist). The diagnosis cannot yet be definitely settled, although it looks more than likely that the tumor is a syphilitic one.

Remarks.—In going over the above cases the following points appear to be of importance:

1. There is no absolute sign distinctive of gastric carcinoma (excepting a microscopic tissue section) which may not be encountered in a gummatous tumor of the stomach. In Cases I. and II. all clinical signs of gastric carcinoma were present in a clear-cut manner. In one of them even the Wassermann test was negative, and the macroscopic appearance of the tumor after opening the abdomen tallied with an inoperable carcinoma. In the other the *x*-ray findings, likewise, indicated the presence of a malignant neoplasm. The lesson to be learned from these cases is, not to forget the possibility of gumma, in making a diagnosis of cancer of the stomach.

2. A positive Wassermann reaction is helpful in establishing the diagnosis of a syphilitic lesion. Its absence, however, does not positively militate against lues; nor does its presence indicate that the gastric affection is a syphilitic one.

A rigorous antiluetic treatment carried out over an extended period of time (2 to 4 weeks or more) gives us the desired information with regard to the differential diagnosis. If there is general improvement and with it a perceptible decrease or disappearance of the tumor, then we are entitled to make the diagnosis of gastric syphilis. The antispecific treatment leaving the patient in a status quo, or perhaps increasing the symptoms, it will rather bear testimony against a luetic nature of the affection in question.

3. Patients with distinct syphilis frequently suffer from other organic lesions of the stomach which are entirely independent of the coexisting general lues. They, therefore, require the usual measures of procedure and treatment in addition to the antispecific régime.

THE TREATMENT OF PYORRHEA ALVEOLARIS AND ITS SECONDARY SYSTEMIC INFECTIONS BY DEEP MUSCULAR INJECTIONS OF MERCURY.*

By BARTON LISLE WRIGHT, M.D.,
SURGEON, U. S. NAVY,
AND
PAUL G. WHITE, D.M.D., A.A.,
DENTAL SURGEON, U. S. NAVY.

THIS very common and widespread disease has, until recently, been considered only in relation to its local destructive action, but the writings of Billings, Rosenow, and others have drawn attention to its importance as a source of serious systemic infection.

Among these infections may be mentioned malignant endocarditis, chronic arthritis, myositis, Hodgkin's disease, systemic antinomycosis, various stomach disorders, neuritis, and other diseases of the nervous system.

From this it is apparent that the cure of this disease, long regarded by the medical and dental professions as more or less incurable, is of most vital importance, not only to prevent its local ravages, but as a prophylactic measure against systemic invasion, with its serious and sometimes fatal results, or where this invasion has already taken place, to remove the source, thereby making the permanent cure of the systemic infection a possibility.

No one organism can be held responsible as the specific cause of this infection. Billings and Rosenow state that the dominant organisms concerned in its production belong to the streptococcus-pneumococcus group. In addition staphylococci, a fusiform bacillus, the *Bacillus aërogenes capsulatus*, and various saphrophytic organisms may be concerned. They believe that the streptococcus-pneumococcus group apparently comprise the important pathogenic bacteria related to systemic infection.

All of these organisms are vegetable parasites.

The theory upon which our treatment of this disease is based has been published† several times previously, and briefly is as follows:

*Read before the Portsmouth, N. H., Medical Society, February 2, 1915.

†MEDICAL RECORD, December 2, 1911. "The Treatment of Tuberculosis and Other Diseases of Vegetable Parasitic Origin by Deep Muscular Injections of Mercury."—MEDICAL RECORD, July 11, 1914. "The Treatment of Diseases of Vegetable Parasitic Origin by Deep Muscular Injections of Mercury."

For every vegetable parasite mercury is the chemical affinity, and when properly injected into the infected host will cure the specific disease. The multiplicity of the organisms concerned in the production of pyorrhea (and it is probable that in every case a multiple infection is present sooner or later) renders the specific treatment directed at any one organism of little if any value.

For the sake of argument, granting the correctness of the above-mentioned theory, then its practical application in the treatment of this particular disease would seem to be ideal, and it should result in the cure of a majority of the cases treated.

Not only this, but it should also cure any secondary systemic infection that might be present, whether caused by the same organisms, as found in the original focus of infection, or transmutation forms of these organisms, the possibility of which has been demonstrated by Rosenow, and, later, independently, by the Pasteur Institute of Paris; for no matter how changed the physical and specific characteristics of these transmuted organisms, it is a matter of biological impossibility for them to change their class; they remain vegetable parasites.

Further, any coexisting disease of vegetable parasitic origin, not related to the pyorrhea in any way, should be benefited and under certain conditions cured by the treatment.

Our faith in the correctness of the theory being absolute, we approached the treatment of this disease, its secondary systemic infections, and any coexisting complicating diseases produced by the vegetable parasitic organisms with supreme confidence.

Our results have been so uniformly and brilliantly successful as to demonstrate the correctness of the theory, both in the restricted sense as applied to this particular disease, and in the broader sense as applied to all diseases of vegetable parasitic origin.

So far we have treated twenty-eight consecutive cases, all of which have been completely cured in remarkably short periods of time. Of these, nine, or 32.1 per cent., had systemic infections in all probability secondary to the pyorrhea, six of these being chronic arthritis, one chronic grastritis, one chronic bilateral facial neuralgia, and one chronic laryngitis. In addition two others had gonorrheal arthritis.

All of these systemic infections, including the cases of gonorrheal arthritis, were also cured.

The longest period of time required to effect a cure was 41 days (Case 24), the shortest 4 days (Cases 9, 10, and 11), average 15 +. Greatest number of injections required to cure the primary infection in one one case 6, smallest number 1. Average 2.7.

The local treatment as administered by Dr. White embraces the following: Careful expression of the pus from the pockets, thorough removal of calcareous deposits and tartar wherever found, the extraction of hopeless teeth and roots, polishing of tooth structure, followed by applying to the margin of the gums equal parts of tr. iodine, tr. aconite, and chloroform, continued every other day.

The injections of mercuric succinimide should be commenced with the local treatment. The initial injection in a male patient should be gr. 5/5, repeated every seventh day, or, depending upon the condition of the patient, the dose of each succeeding injection may be slightly reduced. In females the dose should be from gr. 1/5 to gr. 2/5 less. The cooperation of the physician and dentist is most essential.

Case I. C——, E. W., chief carpenter. Came under observation May 4, 1914. Complaint: Severe pain, soreness, and stiffness of shoulder joints and of the feet and ankles. This condition had existed for some years. Treatment at different times had proven of little benefit. For the past few months had grown much worse; patient hardly able to get out of bed or dress himself. Was under treatment of A. A. Dental Surgeon P. G. White for pyorrhea, which Dr. White considered an extensive and bad case. A diagnosis of chronic infectious arthritis was made, infection probably due to the condition of the gums. Injections of mercuric succinimide were given as follows: May 4, gr. 7/5, slight gingivitis, feels better; May 11, gr. 5/5; May 19, gr. 4/5; May 23, entirely free from all symptoms, Dr. White reports pyorrhea cured; May 24, gr. 4.5. June 2, complains of pain in both hip joints, injection gr. 4/5; June 7, gr. 3/5; June 13, gr. 4/5; June 29, feels perfectly well, injection gr. 3/5. July 8, perfectly well, injection gr. 3/5. Patient states that a large patch of eczema which has been present on the chest for the past thirty years has also disappeared.

Case II. S——, W. H., sergeant, U. S. M. C. Case referred by Dr. White, with diagnosis of pyorrhea, gums soft, spongy, and retracted. Pus exuding from around every tooth. Has a chronic arthritis of left ankle which is considered an autogenous infection from the local infection of gums. Injections as follows: June 29, gr. 6/5; July 6, gr. 5/5, marked improvement; July 11, gr. 4/5; July 17, gr. 4/5, all pain and swelling in left ankle disappeared, gums normal; July 21, apparently cured. The following injections given as a precautionary measure: July 24, gr. 3/5; July 31, gr. 2/5.

Case III. R——, C. E., chief yeoman. Case referred by Dr. White, who has been treating the patient for about six weeks. Extensive and severe infection which has shown slight improvement. Injections of mercuric succinimide as follows: June 29, gr. 5/5; July 6, gr. 4/5; July 11, gr. 3/5; July 13, apparently cured. Three more injections were administered as a precautionary measure: July 17, gr. 3/5; July 24, gr. 2/5; July 31, gr. 2/5.

Case IV. K——, E., G. C. M. P. Referred by Dr. White. Patient presents soft spongy gums, which bleed freely, and are extremely tender and sensitive. Pus in large amounts discharges from around every tooth. Has a polyarthritis, both knees and both ankle joints being infected. It is thought that this condition is probably an autoinfection. Injections of mercuric succinimide as follows: July 28, gr. 5/5, followed by marked improvement; August 3, gr. 4/5. By August 6 all symptoms had disappeared. August 18, no evidence of pyorrhea present, but injections resumed as precautionary measure, gr. 4/5. August 24, gr. 4/5. Pyorrhea and arthritis cured.

Case V. K——, S. Pyorrhea, severe and extensive. Subacute gonococcic urethritis. Gonorrheal arthritis. Injections mercuric succinimide as follows: August 16, gr. 6/5; August 25, gr. 4/5; September 2, gr. 4/5; September 4, pyorrhea cured. September 9, gr. 3/5; September 16, gr. 3/5. No discharge from urethra for past ten days. Urine free from shreds. Arthritis cured.

Case VI. D——, A. W. Referred to Dr. White by P. A. Surgeon Wheeler for local treatment of a severe and extensive pyorrhea on August 19. Dr. Wheeler had on August 18 injected mercuric succinimide, gr. 6/5, the patient also having gonorrheal arthritis. August 19, gr. 5/5. Gingivitis followed; August 26, gums still slightly tender, but pus has entirely disappeared. September 2, gr. 4/5. Pyorrhea and arthritis cured.

Case VII. M——, J. J. Extensive and severe pyorrhea. Injections mercuric succinimide as follows: Aug. 18, gr. 5/5. Marked improvement followed immediately. August 24, gr. 4/5; August 30, cured; August 31, gr. 4/5, as a precautionary measure.

Case VIII. P——, L., Corporal of Marines. Pyorrhea, moderately severe case, involving processes of upper and lower central teeth. Injections mercuric succinimide as follows: August 27, gr. 5/5; September 2, gr. 4/5; September 4, cured. No further treatment.

Case IX. E——, W. C. Pyorrhea, mild. Polyarthritis. Both knees and both ankles involved. Injections mercuric succinimide as follows: September 14, gr. 5/5; September 17, pyorrhea and arthritis cured.

Case X. J——, E. S. Pyorrhea, mild, involving processes of all upper teeth. Injections mercuric succinimide as follows: September 25, gr. 6/5; September 28, cured.

Case XI. G——, T. J., P. M. Pyorrhea, mild, involving processes of lower teeth. Injections mercuric succinimide as follows: September 25, gr. 5/5; September 28, cured.

Case XII. S——, W. J., Chf. Quartermaster. Pyorrhea, severe, involving processes of all teeth, all of which are loose. Complains of indigestion and very poor appetite. Injections mercuric succinimide as follows: September 5, gr. 5/5; September 12, gr. 5/5; September 19, gr. 3/5; September 22, cured. Gastric symptoms disappeared. Has excellent appetite.

Case XIII. C——, R. B., M. A. Arms, lc. Pyorrhea, severe, involving processes of all teeth, all of which are loose. Abscess of right upper jaw and severe bilateral facial neuralgia. Abscess incised and drained. Injections of mercuric succinimide as follows: September 5, gr. 5/5; September 6, neuralgia disappeared; September 12, gr. 5/5; September 19, gr. 3/5, markedly improved; September 26, gr. 4/5; October 2, gr. 3/5, cured.

Case XIV. B——, E. Pyorrhea, moderate, upper and lower central teeth. Polyarthritis involving knees and ankles. Injections mercuric succinimide as follows: October 5, gr. 5/5; October 12, gr. 5/5; October 19, gr. 4/5; October 21, pyorrhea and arthritis cured.

Case XV. P——, O. S. Pyorrhea, severe, involving processes of all teeth. Injections mercuric succinimide as follows: October 8, gr. 5/5; October 15, gr. 4/5; October 21, cured; October 23, an injection, gr. 3/5, was given as a precautionary measure.

Case XVI. A——, L., Coxswain. Pyorrhea, severe, processes of all teeth involved. Gums, extreme recession, soft, spongy, and bleeding. Injections mercuric succinimide as follows: October 12, gr. 5/5; October 19, gr. 5/5; October 26, gr. 5/5; October 31, cured.

Case XVII. B——, J. E. Pyorrhea, mild. Injections mercuric succinimide as follows: October 20, gr. 5/5; October 25, cured.

Case XVIII. W——, J. F. Pyorrhea, severe, involving processes of all teeth. Injections mercuric succinimide as follows: October 26, gr. 5/5; November 3, gr. 5/5; November 6, cured.

Case XIX. R——, F. Pyorrhea, moderate in extent and severity. Injections mercuric succinimide as follows: October 31, gr. 5/5; November 7, gr. 5/5; November 9, cured.

Case XX. D——, D., P. M. Pyorrhea, mild, processes of upper molars and lower central teeth involved. Marked recession of gums. Injections mercuric succinimide as follows: November 4, gr. 5/5; November 11, gr. 5/5; November 14, cured.

Case XXI. M——, M., F. lc. Pyorrhea, severe, moderately extensive. Injections of mercuric succinimide as follows: November 3, gr. 5/5; November 10, gr. 5/5; November 17, gr. 5/5; November 20, cured.

Case XXII. M——, C. O., C. M. A. Arms. Pyorrhea, extensive calcareous deposit and gum recession. Free flow of pus from upper molars and lower central teeth. Injections of mercuric succinimide as follows: November 7, gr. 5/5; November 14, gr. 5/5; November 19, gr. 5/5; November 20, cured.

Case XXIII. O——, A. W. Pyorrhea, calcareous deposit and gum recession extreme. Discharge of pus from around every tooth. States that he is subject to frequent attacks of laryngitis and tonsillitis. Injections mercuric succinimide as follows: November 14, gr. 5/5; November 21, gr. 5/5; November 28, gr. 5/5; November 30, cured.

Case XXIV. F——, L. P. Pyorrhea, extremely severe, very extensive calcareous deposit under the gums, which are extremely tender and sensitive, free flow of pus from around all teeth. Severe arthritis of knee joints. Injections of mercuric succinimide as follows: November 2, gr. 6/5; November 9, gr. 5/5. These were followed by an immediate and marked improvement in the arthritis. By November 16 the joint symptoms had entirely disappeared, and he was referred to Dr. White for local treatment. Injections of mercuric succinimide were continued as follows: November 16, gr. 5/5; November 24, gr. 5/5; December 1, gr. 5/5; December 8, gr. 5/5; December 12, cured.

Case XXV. S——, G. W. Pyorrhea, severe, large amount of pus discharging around every tooth. Injections of mercuric succinimide as follows: November 21, gr. 6/5. This was followed by severe gingivitis and angina. On the twelfth day following, December 3, gr. 3/5. This was followed by rather severe abdominal pain, diarrhea, and rectal tenesmus, patient evidently having an idiosyncrasy for mercury. December 13, gr. 2/5; December 20, gr. 2/5; cured.

Case XXVI. A——, K. E. Pyorrhea, moderately severe, pus from around all molars, which are loose. Injections mercuric succinimide as follows: December 5, gr. 5/5; December 12, gr. 5/5; December 19, gr. 5/5; December 20, cured.

Case XXVII. Mrs. X——. Pyorrhea, moderately severe, gums soft, spongy, tender and with tendency to bleed. Condition had existed some time. Since middle of August had been receiving local treatment from a local dentist. In latter part of August developed a perialveolar abscess above left upper first molar. Old filling removed and root canals treated and tooth refilled. Later the abscess was incised, drained, and cavity swabbed with pure iodine, without improvement. November 11, 1914, condition of gums as above, over left upper first molar, a chronic perialveolar abscess was present, discharging pus through a patulous operative sinus, with a free discharge of pus from around tooth, which was quite loose. The upper right bicuspids were loose, with a free discharge of pus from around them. Injections of mercuric succinimide as follows: November 12, gr. 7/10; November 16, gr. 1/2. Following these pus entirely disappeared, the abscess sinus closed; November 24, injection, gr. 3/5; November 26, cured; November 31, gr. 2/5 as precautionary measure.

Case XXVIII. McC——, L. P. Pyorrhea, severe, extensive calcareous deposit about the neck of every tooth, free flow of pus from around all teeth. The injections in this case were given by P. A. Surgeon G. E. Thomas, U. S. Navy, at the Naval Prison, and through some oversight, three were given before local treatment was commenced on November 28. Injections of mercuric succinimide as follows: November 13, gr. 5/5; November 20, gr. 5/5; November 27, gr. 5/5; December 4, gr. 4/5; December 14, gr. 4/5; December 16, cured. There has not been a recurrence of pyorrhea, secondary systemic infection, or complicating infection in any of these cases.

ORAL OSTEITIS IN ITS RELATION TO ARTHRITIS.*

By BYRON C. DARLING, A.B., M.D.,

NEW YORK.

INSTRUCTOR IN ORTHOPEDICS, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ROENTGENOLOGIST, ST. VINCENT'S AND RUPTURED AND CRIPPLED HOSPITALS.

The need for exact diagnosis and the removal of the focus of infection as the first step toward the treatment of a particular condition, is becoming more generally recognized by the medical profession. A study of the literature discloses active measures being carried on along this line in each branch of the profession. Rosenow, Billings, Hastings, Camac, Joseph Collins, and others, each an authority in his particular field, have recently contributed valuable articles on the subject.

The *need* for exact diagnosis is generally admitted, but the hidden focus often baffles definite localization, and treatment, consequently, has been lacking in directness and efficiency. This paper is written from the angle obtained by the use of the *x*-ray. The field of the *x*-ray is constantly widening and its diagnostic value increasing as its technical perfection is increased and its findings assimilated and checked up.

Some of these hidden foci of infection, while not of a virulent nature, are often of a chronic and incapacitating character and of most serious import. Their clinical manifestations in the order of ther importance, are, first, because more frequent, those of the chronic joints, single or multiple, usually progressive with periods of improvement, directly related to the increase or decrease of the resistance of the patient. That there is a great need for definite diagnosis in these cases is evidenced by a statement made recently by J. B. Murphy, that there had been no advance in the treatment of chronic joints in fifty years, the treatment being expectant and palliative. Next in order, shown notably by the work of Rosenow, are ulcers of the stomach and intestines, endocarditis, myocarditis, myositis, migraine, neuralgia, neuritis, and neurasthenia.

*Read before the Medical Section of the Academy of Medicine, October 20, 1914.

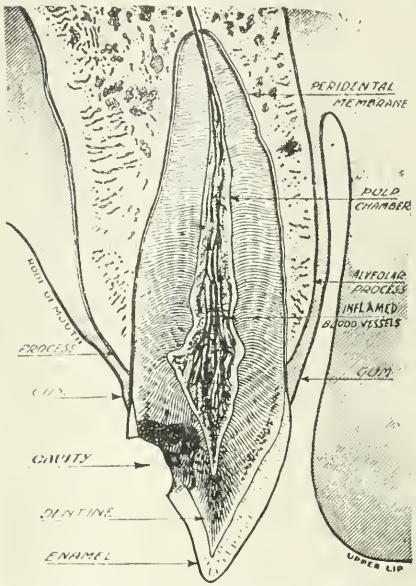

Fig. 1.—Diagram: The anatomical relations of a tooth and the first stage of apical osteitis—infection and inflammation. (Diagram by courtesy of the Ransom & Randolph Co., from "Seven Stages of Decay.")

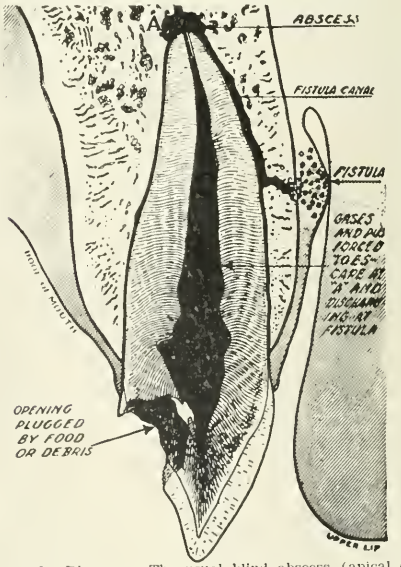

Fig. 2.—Diagram: The usual blind abscess (apical osteitis) has developed the less common fistula and gumboil. (Diagram by courtesy of the Ransom & Randolph Co.)

Much has been written by physicians and dentists upon the mouth as a source of infection in all of these conditions, and it is with this aspect of the

value of the *x*-ray as a means of exact diagnosis that this paper chiefly deals.

The teeth fall between the province of the dentist and that of the physician, who seldom meet for co-operation in diagnosis. Whether the patient, child

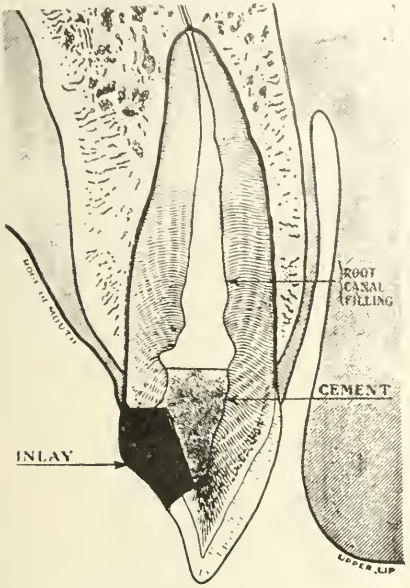

Fig. 3.—Diagram: The root canal has been emptied of septic material; the osteitis, drained, has healed; and the canal, filled, is now aseptic. The root filling (white in diagram), more opaque than the tooth, shows clearly in the radiograph. (Diagram by courtesy of the Ransom & Randolph Co.)

or adult, has ever had a dentist or not, the preponderance of possibilities points to the roots of the teeth, the gums, and the jaws, as harboring some focus of infection. The teeth being some thirty-two in number, having from one to three

Fig. 5.—Wet specimen: 1. Snags or roots, a frequent source of apical osteitis. 2. Extensive pyorrhea (Riggs' Disease). Note the receded ulcerated gum, due to disease and absorption of the alveolar process beneath.

roots to the tooth with pulp above, its nerve in the canal of each root below, and the root socket about each root (Fig. 4), it follows that any decay extending to and causing the death of the pulp or nerve becomes a source of infection which, if untreated, must result in a root abscess, osteitis, with or without fistulas (gum-boils) (Figs. 1, 2, 3).

In the gums and alveolar process where Riggs' disease (pyorrhea alveolaris) is present, an *x*-ray examination is of great importance, showing

Fig. 4.—Dry specimen (child): The normal alveolar process closely surrounds necks of teeth, roots, and apices. Here several teeth have as yet blunt, unformed apices.

as it does the absorption of the aveolar process about the root, varying from an open space the width of a line between the tooth and the socket to that shown by a tooth loose in a bed of swollen and inflamed gum with disappearance of the adjacent bone (Figs. 5 to 8). But more important is the demonstration of the root abscess cavities, early and minute or large with fistulas (Figs. 9 to 12); and finally, the *x*-ray will show if a root has been properly filled to its apex by the dentist. Wherever any suspicious condition brings the teeth into question, the matter should be looked into thoroughly by both the physician and the dentist, leaving no hidden focus undiscovered. Frequently a patient will say, "I have been to the dentist and he says my teeth are in perfect condition"; and yet an *x*-ray examination will show definite lesions (Figs. 13 and 14).

Fig. 6.—Dry specimen: Stripping of all the teeth from alveolar absorption, especially the molars, which have become loose foreign bodies. Compare with Figs. 1 and 5.

To identify the invading germ and prove its derivation from these foci is a laboratory task beset with many difficulties; but the successful work already done by Rosenow, Hartzell, Hastings, and others, supports the idea here emphasized.

The writer does not assert that the mouth is the sole source of infection in arthritic conditions but is mindful of the many foci of infection from which virulent poisons may enter the system. In ascertaining some of these foci of infection, the *x*-ray is of equal diagnostic value. With no attempt at arrangement in order of importance, but rather to recall the various sources of infection and to advocate the necessity of making the search thorough—for any one case may be the sum total of several infections—a routine search may well begin at the head, where we have, first, in the respiratory tract: nose, throat, and tonsils; middle ear and mastoid; accessory sinuses; glands of the neck; lungs, mediastinal glands. An *x*-ray examination is recognized by the otologist as of the greatest value in mastoid condi-

Fig. 7.—*X*-ray in the living: Extreme stripping from pyorrhea (Riggs' Disease). Even the ends of the roots, as well as the entire alveolar processes, are absorbed. Note the uncleanly bridge on the lower front incisors. Compare with Figs. 1, 5, 6, and 8.

Fig. 9.—Dry specimen: 1. Small apical necrosis. 2. Larger area over molar. Compare with Fig. 14 (*x*-ray in the living).

Fig. 11.—Dry specimen: 1 and 1a. Decay of canine. Infection extending to the apex produced large area of necrosis anterior to the antrum. 2. Alveolar absorption from pyorrhea. Other teeth likewise.

Fig. 8.—*X*-ray in the living: Long history of arthritis. 3 and 4. Crowned teeth with root canals not filled, showing slight apical osteitis. 5, 6, and 7. Crowned fifteen years; roots completely stripped from alveolar absorption (pyorrhea) or from extension of apical osteitis; canals never emptied or filled. 8. Root lost through disease.

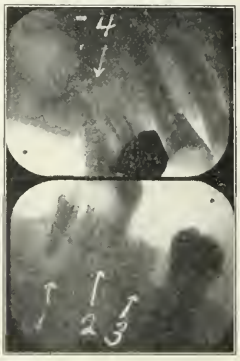

Fig. 10.—*X*-ray in the living: 1, 2, and 3. Snags, no dental treatment. These small foci the only known cause of chronic arthritis of the hip, incapacitating a vigorous working man; the other hip is now involved. 4. First bicuspid. Root canals, not completely filled, show apical disease.

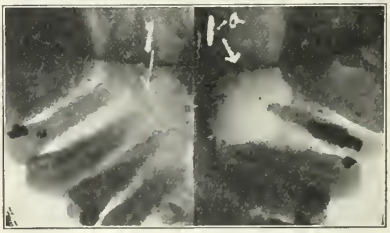

Fig. 12.—*X*-ray in the living: 1. Normal side showing cancellated bone detail. 1a. Large apical abscess (osteitis) following porcelain crown and pivot: infection caused by failure to empty and fill the canal. Such "whited sepulchres" must become diseased. Compare with Fig. 11.

tions, and by the rhinologist as of considerable value in sinusitis. In lung conditions it is the sole means of demonstrating the glands at the root of the lung, as well as supplementing greatly the physical examination of the lungs themselves.

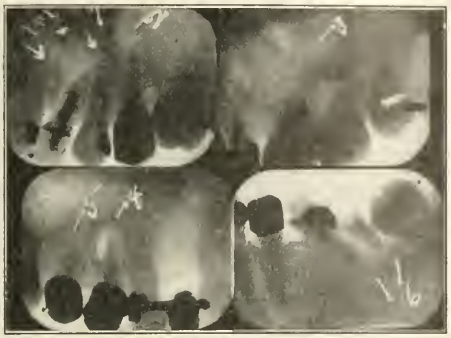

Fig. 13.—*X*-ray in the living: Patient has optic neuritis and total blindness, not syphilitic: no sinus or other infection found. 1, 2, 3, and 4. Crowned, but root canals not emptied or filled: marked areas of apical osteitis. 5. First bicuspid; only one of the two canals filled; whole fused root diseased. Compare with Figs. 10 and 11.

Second in the order of search is the alimentary canal. In the stomach and duodenum, Rosenow has shown that the streptococcus viridans injected into the blood stream of animals will produce ulcers, which, theoretically, at least, may be located anywhere in the gastrointestinal tract. The *x*-ray in its possibilities for the localization of these menacing lesions is commanding attention.

In the recently rediscovered field of intestinal stasis, with its so-called autointoxication, the kinks and adhesions can often be demonstrated by the *x*-ray. This field is too new to be free from errors of judgment in interpretation, and it would seem as if the surgical procedures advocated are too capital, if not entirely wrong, and should be withheld, at least until every other possible source of relief has been tried out and has failed. The possibility of autointoxication from retention of the stomach contents due to pyloric obstructions, duodenal kinks, atony of the muscalature, or gastroeroptosis, can be shown by *x*-ray examination.

In cases of infected gall-bladder, for showing the presence of biliary calculi, the *x*-ray examination is becoming more and more dependable, showing gallstones where they have sufficient calcium salts in their composition. Claims are being made recently for from 50 to 74 per cent. positive results (Pfahler).

In the genitourinary system with its foci, such as abscesses in the kidney from calculi, or possible ulcerations from abrasions caused by calculi in passage through the ureter, the *x*-ray findings are especially satisfactory. Following these as foci of infection are pyelitis, cystitis, urethritis, prostatitis, and seminal vesiculitis, in the diagnosis of which the urologist and bacteriologist have made great strides in recent years.

All these various foci of infection must be carefully considered in order to make an exact diagnosis, no one of them as yet having a monopoly as a focus of infection in arthritic conditions.

In summing up, all mouth conditions should receive the most searching and scientific attention. It is of the greatest importance that there be established a clinical attitude which will insist that no treatment of these obscure diseases is complete without putting the teeth in order by dentistry that is beyond question.

I am indebted to Dr. Virgil P. Gibney for the

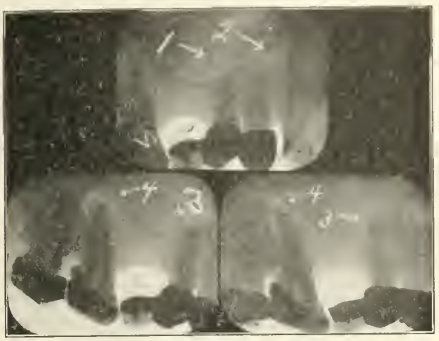

Fig. 14.—*X*-ray in the living; long history of arthritis; many dead teeth and much dentistry, but no root canals emptied or filled; neither pain nor external evidence of disease. 1, 2, 3, and 4. Varying stages of apical osteitis. Compare with Fig. 10.

privilege of showing *x*-ray examinations of the teeth of some of his private patients; to Dr. W. H. Haskin for the use of illustrations from his comprehensive collection of wet and dry specimens; and to Dr. R. Ottolengui, dentist and editor of the *Items of Interest*, for advice and encouragement.

Conclusions.—1. As a first rather than as a last resort, special attention must be paid to the condition of the teeth. The hidden focus of infection may be a blind alveolar abscess (osteitis).

2. Good health demands the constant close attention of a conscientious and scientific dentist.

3. Much old and unscientific dentistry, such as bad crown and bridge work and root fillings that are not scientific, must be removed, and the conditions remaining properly treated; failing this, merciless extraction and false teeth but a clean mouth.

4. Pyorrhea alveolaris (Riggs' disease) is a menace to good health; it is a chronic ulcer of the gum and finally of the bone, and assuredly a focus of infection.

5. There should be cooperation with mutual recognition of responsibility between the physician and the dentist.

6. The search for the hidden focus of infection, while being very extensive and careful in the oral cavity, should not be confined to it but should extend over every possible seat of infection.

7. Even though the hidden focus be found and the cause of the systemic infection removed, the seed of the disease has already been sown broadcast and many expedients will be required before a recovery is effected.

122 East Thirty-fourth Street.

The Albumin Reaction of the Sputum.—L. Löwenbein states that in the differential diagnosis between an uncomplicated chronic bronchitis and tuberculosis an albumin content in the sputum of one per cent. or more indicates the presence of tuberculosis. The increase and the decrease in the albumin content are of greater value in prognosis than the mere size of this content. The regular estimation of the albumin content is of value in gauging the effect of an artificial pneumothorax. At least 5 cubic centimeters of sputum are necessary for the proper estimation of the albumin content.—*Zeitschrift für Tuberkulose.*

NEGLECTED LATERAL CURVATURE.*

By MAX STILUNSKY, M.D.,

NEW YORK.

We have progressed in every branch of medicine, but in the method of diagnosing incipient scoliosis we stand still. This in spite of the fact that we have had for some time the school system of examination by corps of physicians who are appointed for the distinct purpose of detecting diseases and deformities in children at the earliest possible stage. In spite of this, however, lateral curvature, which is so serious and which is the most widespread deformity that affects the human race, falls still to the lot of the mother, teacher, or dressmaker for an early diagnosis, just as was done hundreds of years ago.

Unlike tuberculosis of the spine, which causes systemic disturbances such as pain, sweats, night-

Fig. 1.—Type of Class I.

cries, etc., which compel the parents to seek medical advice, thereby causing a discovery of the "knuckle," lateral curvature usually produces no disturbances at all in the incipient stage. The future sufferers may even enjoy perfect health. Most important of all, the child does not know, and is generally wholly unconscious, that he is the victim of this deformity. It is not at all an uncommon experience to see a youngster who hears for the first time that his spine is not straight, quickly feel with his fingers his scapula and his shoulders, blush with surprise, turn round to inspect himself in the mirror, hardly believing his senses that there is anything wrong with his back. And yet perhaps for years changes of the most serious nature have been progressing in the victim's vertebræ, intervertebral discs, ribs, spinal ligaments and muscles, gradually compressing the lungs, displacing the heart and the viscera. They were moulding the patient's stature to the form which was surely to be his in the near future—namely the twisted spine, the tilted trunk, the squat figure.

There is a regulation made by the Boards of Education that no child's spine is to be exposed. The school physician, therefore, in examining for scoliosis, can only feel the child's back through the clothing. Such an examination at best can only reveal gross changes in the trunk, but cannot detect early lesions. Even when the spine is exposed, unless one has a sound orthopedic judgment, cases will be passed over as normal when in reality serious deformity exists. This happens when the spinous processes are bent in the opposite direction to the rotation of the vertebræ. In such instances, if one judges from the direction of the spinous processes, the spine is pronounced straight when in reality the rotation of the vertebræ, which is the serious element of the trouble, is advanced far. Such conditions are frequently illustrated by roentgenograms and pathological specimens in the museums.

We must not forget that the muscles, ligaments, and adipose tissue have a tendency to hide the deformity, while the patient's compensatory attitude, which he unconsciously assumes, minimizes the prominence of the curves. This is the reason why scoliosis is so much worse in the skeleton, as revealed by the roentgenograms, than appears when one merely examines the patient's back. We often stand aghast at the gross deformities of a spine and trunk, as revealed by the *x*-ray of patients who seemingly have but a slight curve.

What chance, therefore, has a child for an early diagnosis when the spine is examined through the clothes? Especially as it has been demonstrated of late that in so many instances the trouble begins in the sacrum and in the first lumbar vertebra, in which region the clothes are the thickest. No wonder, therefore, that in the thousands of cases which I have examined the fact which is most conspicuous in the history of practically all the cases is the accusing truth that the trouble was not detected in its incipiency, as should have been done in a civilized society, but rather the deformity was allowed to develop to the point of discovery.

In other words, the deforming forces undermined the symmetry of the skeleton to that extent that in spite of the covering of the soft tissues and the clothes of the patient, the trouble was discernible even to the eyes of the layman. How many thousands of children are there even now in every city who carry in their spinal columns rachitic vertebræ or malformed vertebræ which will be the cause of scoliosis in the future? How much harm is done these children in not exploring their spines as a routine! For without an examination of the back, anatomical weaknesses as they begin to manifest themselves cannot be suspected. As the result of this neglect, harmful influences which often precipitate the entire catastrophe, are even encouraged. For instance, these children are forced to sit up in school for hours at a time, when their spines can but ill afford to support their superincumbent weight. Also by our indifference to the welfare of the children's spines, we necessarily rob the future scoliotics of the benefit of early treatment. This has yielded such excellent results that supporters of early treatment challenge any medical or surgical condition where an early treatment has proved

*Patients exhibited before the Harlem Medical Association, February 3, 1915.

more efficacious than in scoliosis. At the stage when scoliosis is "discovered," structural changes have already advanced so that children face years of tedious treatment by gymnastics or torturing jackets. And though the results are more encouraging now with the use of the Abbott method than with the jackets applied in the erect position, as advocated by Schulthess, Schanz and Lovett, still the patient with structural changes, in the vast majority of cases, must carry his pathology and his invalidism to the grave. For there is no treatment which can bring back a segment of a vertebra once really atrophied, or make flexible that part of the spine which has become ankylosed, or bring back that part of an intervertebral disc which, due to pressure, has entirely disappeared.

The harm which results to patients from our indifference to this problem falls into three classes. I append photographs and histories of patients taken from the dispensary of the Hospital for Deformities and Joint Diseases, illustrating each class.

Class I.—M. T. has a giant scoliosis with rigid structural changes. Though her trouble was recognized seven years ago, nothing at all was ever done for the child in the way of treatment. Her people believed that she would outgrow her trouble, and they simply did not know that a condition of that kind was in need of attention. We have a number of patients of that kind. It only shows the dire necessity of popularizing the early treatment of scoliosis.

Class II.—C. P. has a giant scoliosis. Her deformity was recognized at the "beginning," and her father immediately bought her a brace which she wore for a year, but the trouble grew rapidly worse. Braces do harm in early scoliosis, and consequently fate is even more cruel to patients of this class. The majority of cases are now treated in that slipshod fashion. The parents are anxious to do everything to prevent their child from

Fig. 2.—Type of Class II.

becoming a cripple. The voice of the instrument-maker with his sure "guarantee" is always to be heard. The child lands in some turn-verein where it performs perfunctory exercises, and the short but fruitful period where good results might have been attained from scientific treatment is thus gambled away.

Class III.—C. G. has a large curvature with advanced structural changes. Though her deformity is of a chronic type, both she and her mother assured me that the trouble was only discovered two weeks ago by the dressmaker, and up to that time they never had the slightest inkling that her spine was not straight. It

Fig. 3.—Type of Class III.

seemed unbelievable that such an advanced case could exist for so long a time without being detected. But such are the facts; and I can reproduce any number of cases with similar histories.

Practically all cases of scoliosis fall into this class, more or less. For all cases, even when they are brought to us in their "incipiency," could have been detected earlier if a routine examination of the school child's back by competent orthopedists had been installed.

236 West Seventieth Street.

SOME OBSERVATIONS ON CLINICAL TREATMENTS FOR SYSTEMIC GOITER (GRAVES' DISEASE).*

By MARY SUTTON MACY, M.D.,

NEW YORK.

NEUROLOGIST, DEMILT DISPENSARY.

In presenting these observations on clinical treatments for systemic goiter, frequently called exophthalmic goiter, hyperthryroidism, Basedow's or Graves' disease, the author lays no claim to originality or to wide experience in handling exophthalmic cases. The facts (1) of having a number of similar cases under observation at one time, and (2) of the great divergence of opinion amongst authorities as to kinds of medicinal or surgical methods of treatment, suggested a line of ob-

*Read before the Women's Medical Association of New York City, at the New York Academy of Medicine, February 17, 1915.

servation and investigation which is here reported. The name "systemic goiter"—introduced by Bainbridge—seems to me more scientific than other terms and for this reason is here given preference.

Of the forty-four cases included in this presentation, two were males, and forty-two were females, varying in age from twenty years and eight months to forty-three years and three months at the time of coming under treatment; eleven cases were under fifteen years of age, one of which was a boy; seventeen cases between fifteen and twenty-five years, included the second male case; ten cases between twenty-five and thirty-five, and six cases over thirty-five years of age.

The whole number are divisible into six series, chiefly according to kind of medicinal treatment used, though each series differs from the others in certain particulars of history as well. For the sake of brevity, only one case history from each group is given to illustrate the series, and each illustrative case was selected at random from amongst the others of the group.

Series I.—Ten cases, all females. (1) Bad family history. (2) Early pubertal shock. (3) Enlarged thyroid gland. (4) Persistent and observable thymus. (5) No heart murmur. Pulse under 120. (6) Hemoglobin under 90 and over 75. (7) Mononuclear leucocyte count under 3500; polymorphonuclear over 3500. (8) Urinary findings negative. (9) No exophthalmos present. (10) Tremors and muscular weakness both present. (11) Mentally unchanged or slightly emotional or irritable. (12) Personality unaltered. (13) Medicinal treatment chiefly Iodic Acid and Osmic Acid injection, or Hydrobromate of Quinine. (14) Results: 6 discharged cured; 3 improved, still under treatment; 1 death, from pneumonia.

Case cited: N. D. Case 21, female, age 30 years; under treatment April 29, 1913, to July 31, 1913. No return of symptoms since then.

Series II.—Nine cases, all females: (1) Good family history. (2) Late pubertal shock. (3) No enlargement of thyroid gland. (4) Thymus not observable clinically. (5) Heart, negative. Pulse over 120. (6) Hemoglobin under 75. (7) Mononuclear leucocyte count under 2000; polymorphonuclear over 3500. (8) Urinary findings negative or slight traces of albumin; no glycosuria. (9) No exophthalmos present. (10) Tremors very marked. Great muscular weakness. (11) Mentally depressed, emotionally disturbed. (12) Personality changed. (13) Medicinal treatment, chiefly Sodium Glycerophosphate or the Iodides. (14) Results: 1 spontaneous cure; 2 improved and lost track of; 3 improved and still under treatment; 1 unimproved, probably a surgical case; 2 died, 1 of scarlet fever and 1 of nephritis.

Case cited: D. H. Case No. 13, female, age 16 years 6 months; under treatment from March 27, 1914, to June 29, 1914, spontaneous cure at that time; no recurrence since.

Series III.—Eight cases, all females: (1) Bad family history. (2) Early pubertal shock. (3) Enlarged thyroid gland. (4) Persistent and observable thymus. (5) No heart murmur. Pulse under 120. (6) Hemoglobin under 100 and over 85. (7) Mononuclear leucocyte count over 3500; polymorphonuclear over 3500. (8) Urinary findings negative, or slight glycosuria; no albumin. (9) No exophthalmos present. (10) Tremors and slight muscular weakness both present. (11) Mentally depressed and emotional. (12) Personality altered. (13) Medicinal treatment chiefly Beebe's Iodothyreoglobulin Serum. (14) Results: 4 discharged, cured; 2 improved, still under treatment; 2 lost sight of.

Case cited: D. N. N. Case No. 8, female, age 32 years; under treatment since Jan 17, 1913. Improvement marked until relapse while away and not under strict regulation, Aug. 20, 1913. Since return to City, and resumption of rigid treatment, Sept., 1913, lost ground regained and improvement continued until she moved away from town and was lost sight of in March, 1914.

Series IV. Eight cases; 1 male, 7 female: (1) Family history negative. (2) Late pubertal shock. (3) Thyroid enlargement slight. (4) Presumably persistent thymus. (5) Organic heart murmur. Pulse under 115. (6) Hemoglobin normal. (7) Mononuclear leucocyte count under 4000; polymorphonuclear over 4,000. (8) Urinary findings negative. (9) Exophthalmos present. (10) Tremors marked and muscular weakness present. (11) Mentally irritable. (12) Personality changed. (13) Medicinal treatment chiefly Pituitary Gland. (14) Results: 4 discharged, cured; 1 improved, still under treatment; 1 lost sight of; 2 deaths, 1 of acute Bright's Disease; 1 of pneumonia.

Case cited: J. D. Case No. 12, female, age 18 years 9 months; under treatment since March 12, 1913, until discharged, cured, Jan. 25, 1914.

Series V.—Six cases; 1 male, 5 female: (1) Family history negative. (2) Early pubertal shock. (3) Enlarged thyroid gland. (4) Thymus not observable. (5) Organic heart murmurs. Pulse over 120. (6) Hemoglobin normal, or above 95. (7) Mononuclear leucocyte count under 2500; polymorphonuclear over 3500. (8) Urinary finding negative or slight albuminuria. (9) Exophthalmos present. (10) Tremors and slight muscular weakness both present. (11) Mentally depressed. (12) Personality changed. (13) Medicinal treatment chiefly thymus gland. (14) Results: 4 discharged, cured; 1 improved, still under treatment; 1 dead, acute Bright's disease.

Case cited: C. M. Case No. 20, female, aged 13 years, 5 months; under treatment from April 7, 1913, till Oct. 10, 1913. Transferred to hospital with acute Bright's disease at that time; died Oct. 16th.

Series VI.—Three cases, all female: (1) Family history good. (2) Early pubertal shock. (3) No thyroid enlargement. (4) No observable thymus. (5) Heart negative. Pulse over 120. (6) Hemoglobin under 75. (7) Mononuclear leucocyte count under 3500; polymorphonuclear over 4000. (8) Urinary findings negative. (9) Exophthalmos present. (10) Tremors present but no marked muscular weakness. (11) Mentally irritable and emotional. (12) Personality altered. (13) Medicinal treatment symptomatic or none. (14) Results: 1 discharged, cured; 2 improved, still under treatment.

Case cited: R. L. Case No. 9, female, aged 15; under treatment since Jan. 29, 1913, till discharged, Oct. 7, 1913, as cured. No return of symptoms since that time.

Series I. Case 21—N. D., female, single, stenographer, aged 30; diagnosis—Systemic Goiter, made April 29, 1913. *Family History.* Bad. Father, neurasthenic, dead. Mother, insane, dead. Brother, epileptic. Sister, neurasthenic, married, two children. Tuberculosis in collaterals on maternal side. Epilepsy on paternal. *Personal History.* Normal birth; oldest child; breast fed. Walked and talked normally at one year. Teeth, both sets, normal. Childhood diseases; no convulsions. Menstruation began at thirteen, irregular for three years, with a period of complete absence for six months, during illness of fourteenth year; regular since sixteenth year at five week periods; little pain except prior to and during appendical attack, (at twenty-two), which was operated. History of mental shock—fright—at fourteen, followed by illness of eight months, with weakness, headaches, tremors, dyspnea, tachycardia, general nervousness, including tearfulness and various emotional disturbances, amenorrhea, and intermittent febrile condition. At eighteen had second attack of measles, followed by marked aggravation of myopia, first evidenced during former illness. Eyes, prior to fourteen years of age, were apparently normal and vision good. At twenty-two attack of appendicitis; operated, good recovery, but marked nervousness and emotionalism a concomitant and a sequel.

History of present illness. Onset slow. Thyroid gland enlarged slightly on right side and isthmus, and considerably on left side. Thymus percussable and obviously persistent. Frequent periods of marked dyspnoea, due to "weight on chest." Height, 5 feet, 7 inches. Weight 125 pounds net. Heart normal, no murmurs. Blood pressure 110-115; radial pulses, synchronous, soft, smooth, rapid—varying from 98-110—regular. Hemoglobin 85. Red blood corpuscles, 3,850,000; white blood corpuscle count 6500; polymorphonuclear, 55%, or 3575; lymphocytes 40%, or 2600. Temperature, constantly subnormal, 96-98. Urinary findings usually negative, occasional traces of albumin, usually explainable by indiscretions in diet. Bowels

regular, no constipation, rather tendency to diarrhoea. No exophthalmos, but extreme myopia, and a persistent diplopia, which does not readily or constantly yield to prisms. Marked hypersensitiveness to light and sound, especially at menstrual periods, but not to smell, taste or contact. Mentally irritable and emotional, attentively restless, though not physically so, at times almost apathetic for voluntary motor activity.

Tremors marked, especially in smaller groups and in quadriceps extensors of left thigh. Frequent pains in shoulders and hips, with sudden accessions of muscular weakness. Nutrition, generally good, loss of weight at first; digestive functions normal. Menstruation regular, but scant. Prespiration profuse. Skin and hair dry, latter falling and turning gray. Urticaria, intermittently present, dermographia constant. Hypersensitive to cold. Frequent attacks of bronchitis.

Treatment. Medicinal. Digitalis was tried to point of physiologic action, with little beneficial effect. Hydrobromate of quinine 5 gr. and ergot 1 gr. (Forchheimer method) resulted in considerable benefit, but after a while lost its effect. Tri-weekly hypodermic injects of iodic acid 1 per cent. sol. in 2 minim doses alternated with osmic acid 2 per cent. sol. in 2 minim doses, gradually increasing to 5 minims each, successfully effected a cure.

Hygienic. Complete rest in bed, with alternating daily treatments of electricity (high frequency, low vacuum tube and short spark), and of hot and cold packs; massage; simple, plain diet, without stimulants, during the early months of the treatment. Later complete rest for several hours each day, and cool or cold baths, with continuation of massage and generous diet. Moderate exercise and rest period spent in the open air—suggestion used throughout to control emotionalism.

Result. Improvement marked in first four weeks of treatment; cure attained in three months. No recurrence of symptoms since.

SERIES II.—Case No. 43. D. H., female, single, age 16 years 6 months. Diagnosis, systemic goiter, made March 27, 1914.

Family History. Good. Parents living and well. Sister living and well; no other sisters or brothers. Tuberculosis amongst paternal collaterals. Father had slight attack of tuberculosis as an eighteen year old lad, but by living on a farm for a year and a half, was completely cured.

Personal History. Normal birth; first child; breast fed. Teeth, talking and walking, all normal. Childhood diseases; no convulsions. Menstruation began at fourteen, normal and regular. Studying hard at school for past year preparatory to taking college entrance examinations; ambitious to enter college Fall of 1915. Sudden death of playmate, last summer following an accident, had an unusually disturbing effect upon girl, who was slightly feverish, restless, and irritable for several days following.

Present Illness. Onset gradual. Thyroid gland not enlarged but a visible arterial thrill over gland on both sides. Thymus not percussable. Height 5 feet 3 inches. Weight 110 pounds net. Lungs and heart negative. Blood pressure 120-135, radial pulses, synchronous, rapid, soft, compressible, no thrills, rate 120-136. Hemoglobin 60; red blood corpuscles 4,500,000; white blood corpuscles 6000, polymorphonuclear, 65 per cent., or 3900, lymphocytes 30 per cent. or 1800. Temperature persistently over 100°, running as high as 101°. Urinary findings, slight traces of albumin in all voided specimens, but negative in all sterile specimens; diarrhea persistent. Abdomen and pelvis negative. Slight leucorrhea present and constant since illness in summer. Tremors marked, especially of tongue, hands and thighs. Hypersensitive to heat and light. Change of disposition marked. Has become irritable and exacting, easily angered, and inclined to be pensive, none of which traits were characteristic or noticeable before illness. Menses normal, no pain. Eyes show no exophthalmos, though von Graefe's and Möbius' signs were both present. Vision, normal prior to illness and no changes appreciable now.

Treatment. Medicinal. Iodides in material doses produced some beneficial effects before they were withdrawn. Sodium glycerophosphate in 20 gr. doses *t. i. d.* constituted the chief medicinal treatment. Hygienic. Complete rest in bed and massage with regulation of diet. Baths for reducing febrile condition. Suggestion used to palliate the emotional phenomena.

Results. Cure spontaneous thirteen weeks after diagnosis, with no recurrence of symptoms since.

SERIES III.—Case 8. D. N. N., female, single, kindergartener, aged 32 years. Diagnosis—Systemic goiter, with hysteric complication, made Jan. 17, 1913.

Family History. Bad. Father insane, epileptic, living. Mother, neurasthenic, dead—of pneumonia. Five brothers living, three of them married, two neurasthenic—1 dead, of diphtheria. One sister living, psycho-epileptic, one dead of diphtheria. Tuberculosis and cancer on maternal side. Epilepsy on paternal side.

Personal History. Normal birth, fifth child, breast fed. Teeth, walking, talking, etc., normal. Tonsils and adenoids removed 17th year. No convulsions. Menstruation began at thirteen; irregular for several years, always painful, occasionally too profuse. Alone at home with father in an epileptic attack when only fourteen; had never previously witnessed a seizure, though aware of this occurrence; was badly frightened and suffered later from the shock. Ill for several days and very nervous and timid for many months. Operated for appendicitis and cystic right ovary at twenty-seven, having previously been thrown from horseback and under osteopathic treatment for several months for fractured coccyx. Two operations on nose, one a submucous resection (at thirty), for relief of chronic catarrhal conditions of nose and larynx; from the latter a small cyst was removed at that same time. Has worn glasses for a marked myopia since about fifteen, but no history obtainable of headaches or other evidences of eyestrain prior to fourteen years of age.

Present Illness. Onset gradual. Thyroid gland enlarged slightly and enlargement fluctuates at times, being bilaterally prominent, at times unilateral and occasionally unobservable. Thymus persistent and percussable. Height 5 feet 9 inches. Weight 128¼ pounds net. Frequent attacks of "laryngitis" and a chronic "bronchial cough." Except of occasional dry bronchial räles over trachea and large bronchi, lungs are negative. Heart, normal size, no murmurs. Blood pressure 115-125. Radial pulses synchronous, rapid, soft, no thrills, rate varies from 96-120. Hemoglobin 80, red corpuscles 4,000,000 and white blood corpuscles 8,000, polymorphonuclear, 45 per cent. or 3,600, lymphocytes 50 per cent. or 4,000. Temperature, never normal, varies from 94.6° to 97.8°. Bowels constipated. Urinary findings negative. Abdomen negative, except for sensitive spot over right ovary, which is worse just prior to menstrual period. No exophthalmos. Marked myopia. Diplopia, which yields to prisms, except when generally over fatigued. Emotionally very irritable. "Hysterical" over trifles. Marked dermagraphia, constant eruptions on neck or chest. Tremors marked, especially in small muscles, eyelids and tongue. Hypersensitive to heat. Mentally inclined to introspection and self-conscious. Morbidly affected by sounds and light. Religious and erotic. Menses irregular, profuse, painful. Leucorrhea constant, especially aggravated when up and about.

Treatment. Medicinal. Digitalis tried, with no results, and abandoned for hydrobromate of quinine 5 gr. and ergot 1 gr. Slight improvement, followed by relapse in August, 1913, when away from the city and not under strict medical supervision and control. Beebe's iodothyreoglobulin serum method used for three months prior to relapse, with good preliminary reactions. Patient was still receiving serum tri-weekly when lost sight of. Russian mineral oil controlled constipation. Since return to city in September, 1913, lost ground had been regained, though her teaching had had to be resumed and rest could not be strictly enforced.

Hygienic. Complete rest in bed. Dietetic regulation to adjust bowels and decrease emotional excitement. No stimulants allowed. General massage for a period. Hot baths and hot packs for soothing effect. Suggestion carried to point of mild hypnosis to control hysterical symptoms and eroticism. Financial status of patient made necessary premature return to her teaching, but general hygiene was controlled and rest enforced as much as possible. Still under treatment—fourteen months after diagnosis—when she moved away from the city.

Results. Marked improvement immediately prior to relapse, which was not as serious as it might have been. Since then convalescence slow but appreciable at the time she was lost sight of in March, 1914.

SERIES IV.—Case No. 12. J. D., female, single, musician, age 18 years 9 months. Diagnosis, systemic goiter, made March 12, 1913.

Family History. Negative. Parents dead, mother of pneumonia and father of jaundice. Three brothers

living, all married and well. Two sisters dead, of exanthemata, as children. No history of tuberculosis, epilepsy, nervous disease, syphilis, or cancer obtainable.

Personal History. Normal birth, presumably, as patient never heard to the contrary; youngest child. Mother died when she was two years old; breast fed. Teething, walking, talking, presumably normal. Childhood diseases, only diphtheria and measles. Menstruation began at twelve, irregular, not painful; intercurrent leucorrhea for first three years, none since; flow scanty always. In a runaway accident two years ago. Had been studying very hard at her music and gone to the country to rest before beginning to teach music. Has been nervous and "fidgety" ever since accident, though never so before that time. Frequent attacks of dyspnoea since then, and at such times "feels frightened" without cause.

Present Illness. Onset sudden, following fright. Patient paid little attention to symptoms until she became engaged, then observed that her symptoms were apparently worse at some times than at others. Thyroid gland fluctuates, at times enlarging markedly while under observation, then receding. Left side enlarged very slightly at all times. Thymus percussable and persistent. Height 5 ft. 8 in. Weight 120 lbs. net. Frequent cough, said to be caused by "weight on chest." Heart, slightly hypertrophied, mitral murmur, compensation adequate. Blood pressure 125-140. Radial pulses, synchronous, rapid, small, rate from 98-112. Hemoglobin tests not made; no clinical signs of anemia. White blood corpuscles 8,000. Polymorphonuclear, 50 per cent. or 4,000 lymphocytes, 45 per cent. or 3,600. Temperature 98.2°-99.6°. Bowels alternately constipated and diarrhoea. Urinary findings, negative. Abdomen and pelvis negative. Slight exophthalmos; von Graefe's sign present. Slight hyperopic astigmatism, corrected by glasses since fourteen years old. Tremors present, dermagraphia present. Hypersensitive to heat, smell, and light. Mentally and emotionally introspective, irritable, easily fatigued, apprehensive, tearful, slightly erotic—complains of erotic dreams—timid, and anxious.

Treatment. Medicinal. Sodium glycerophosphate in 15 gr. doses, followed by pituitary gland substance 2 gr. *b. i. d.*

Hygienic. Rest, dietetic, temporary cessation from visits of fiance. Warm baths—suggestion to control emotionalism.

Results. Marked improvement. January 16, 1914, patient discharged as cured, and told to report bimonthly for one year. No recurrence of symptoms.

SERIES V.—Case No. 20. C. M., female, single, age 15 years 5 months. Diagnosis, systemic goiter, made April 7, 1913.

Family History. Negative. Parents living, foreign born—Spanish, apparently well. Only child, only pregnancy. No history of psychosis, tuberculosis, syphilis, or epilepsy obtainable.

Personal History. Normal birth. Breast fed. No convulsions, but poorly nourished, "ailing" baby, though "not sick." Talked one year, walked eighteen months, teeth, ten months. Childhood diseases, rheumatism and pneumonia. Tonsils and adenoids removed at eleven years. Menstruation began five months ago; regular, no pain, normal flow. Bad fright with fire in neighborhood four months ago, followed by onset of present trouble.

Present Illness. Onset sudden but insidious. Thyroid gland enlarged, more on left than on right side. Thymus not percussable. Height 5 ft. 4 in. Weight 125½ lbs. net. Lungs negative. Heart showed functional murmur at apex—not always present. No hypertrophy. Blood pressure 130-145. Radial pulses, synchronous, hard, full, rate 120-125. Hemoglobin tests not made, no clinical symptoms of anemia. Red blood cells 4,000,000, white blood cells 6,000, polymorphonuclear, 60 per cent. or 3,600, lymphocytes 35 per cent. or 2,100. Temperature 97.9° to 99.8°. Abdomen and pelvis negative. Urinary findings, traces of albumin—insufficient to quantitate. Bowels constipated, slight exophthalmos, von Graefe's, Möbius', and Stellwag's signs all present. Hyperopic astigmatism, for which glasses have been worn for four years. Marked increase in general adipose since appearance of menses. Tremors marked in all superficial muscle groups. Dermagraphia. Hypersensitive to cold and sound, but not to light. Mentally irritable, timid, melancholic; formerly vivacious and fearful.

Treatment. Medicinal. Thymus gland preparations 5 gr. daily. Russian mineral oil to control bowels.

Hygienic. Rest. Diet regulated to control adipose and to regulate bowels. Tri-weekly treatments with galvanism.

Results. Marked general improvement and decrease of hyperthyroid symptoms, prior to development of an acute Bright's six months after diagnosis, of systemic goiter. Patient transferred to a hospital and died within the week. No post-mortem could be obtained.

SERIES VI.—Case No. 9. R. L., female, age 15 years. Diagnosis, systemic goiter, made January 29, 1913.

Family History. Good. Parents living and well. Three sisters living and well—two married. Two brothers dead, one in infancy, of convulsions, and the other of pneumonia, aged twenty-three. Collateral and ancestral histories negative.

Personal History. Normal birth. Fifth child, breast fed. Walked, one year; talked, ten months; teeth, nine months. Considered a precocious child. Childhood diseases, no convulsions and chorea. Tonsils and adenoids removed, aged 11. Operated for appendicitis five years ago. Menstruation began two years ago (1911); regular, no pain, normal. Badly frightened a year ago (1912) when little sister was knocked down by an automobile and hurt while children were on their way home from school. Since then her disposition has changed. Previously was thoughtful, considerate and quiet; now restless, constantly stealing off to moving picture shows, craving excitement, irritable, and sleeps badly.

Present Illness. Onset gradual. Thyroid gland not enlarged. Thymus not percussable. Height 5 ft. 6 in. Weight 100 lbs., net. Heart negative. Blood pressure, not taken. Radial pulses, synchronous 124-138, soft, compressible, irregular. Hemoglobin, 65; red blood cells, 4,000,000; white blood cells, 8,000, polymorphonuclear, 50 per cent. or 4,000, lymphocytes, 40 per cent. or 3,200. Temperature normal. Bowels normal. Urinary findings negative. Abdomen and pelvis, negative. Slight exophthalmos, von Graefe's and Stellwag's signs both present. Diplopia, which yields to prisms in glasses, myopic astigmatism. Tremors marked. Knees frequently give way beneath her. Fatigues easily. Mentally and emotionally restless and irritable. Dermographia and acne both present.

Treatment. Medicinal. Symptomatic.

Hygienic. Rest and isolation. Massage. Dietetic, hot baths and hot packs, and later, triweekly, galvanism. Later still suggestion.

Results. Disappearance of all but mental symptoms in six months. Emotional and mental conditions have since yielded to suggestion. Patient discharged in Oct., 1913. No return of symptoms since.

From a psychiatric point of view the following analysis of conditions existing in the whole number of forty-four cases is of interest.

6 or	14%	showed definite history of a psychopathic taint in the family, and
18 or	41%	presented a neuropathic family history.
24 or	55%	showed a psychoneurotic family history.
36 or	82%	developed positive emotional disturbances with the systemic goiter.
34 or	78%	showed actual reversal of previous personal characteristics.
19 or	43%	were highly irritable.
23 or	53%	developed depressive states.
17 or	39%	were apprehensive.
13 or	30%	developed excitable states.
7 or	16%	had hallucinations.
13 or	30%	had a genuinely psychopathic make up.
44 or	100%	gave history of nervous shock during puberty followed by a more or less prolonged period of illness either diagnosed immediately as systemic goiter and treated as such, or appearing as a masked hyperthyroidism at the time.
27 or	62%	suffered from shock immediately before onset of symptoms of systemic goiter.
17 or	39%	gave history suggesting a hyperthyroidism masked for ten years or more, and of these 15 (or 34 per cent. of all cases) had suffered from an infection immediately before onset of systemic goiter symptoms.

Of the cases suffering from shock immediately before onset of symptoms, 22 (or 50 per cent. of all cases) were under sixteen years of age.

Of the thirty-six cases giving positive emotional disturbances, twenty-six had marked enlargement of the thyroid gland, and eight more showed slight enlargement thereof; in only two of these cases was no increase in thyroid observable. Of the twenty-six markedly enlarged thy-

roids in this group, eighteen had likewise a persistent and evident thymus enlargement, and in six more many symptoms suggested it, but it could not be positively so diagnosed clinically.

These figures have been of interest to the author for three reasons:

1. Bainbridge, Kocher, Marine, Mayo, and other surgical authorities agree that a markedly enlarged thymus contraindicates surgical measures, although Osler states that surgical measures should be considered if patient is not better after three months careful medical treatment, and makes no mention—that the author has observed—of enlarged thymus as a contraindication to surgical interference. In eighteen (or 41 per cent.) of the forty-four cases here reported, there was positive clinical evidence of decided thymus enlargement, and in twenty-six cases (or 59 per cent.) the signs were positive (see 18 noted above) or so suggestive as to be considered possible cases of thymus enlargement. It has also been the experience in this series of cases that those presenting enlarged thymus were usually the most obstinate and resistant to medicinal treatment.

2. MacCallum states: "The only lesions in this disease which are palpable and constant, are those of the thyroid; and of the lymphoid apparatus and thymus." Marine and Lenhardt state: "The constancy with which lymphoid hyperplasia occurs in exophthalmic goiter, the definite parallelism between the degree of lymphoid hyperplasia and the thyroid hyperplasia in their progressive stages, cannot now be passed as accidental." Mackenzie states: "It seems probable that in Graves' Disease, the thyroid, for some reason, at present obscure, takes on an increased functional activity." Joffroy and Acard found no distinction in the thyroid glands of Basedow patients and those of simple bronchocele. Greenfeld found proliferation of the tubular spaces and a mucoid material replacing the colloid matrix. Oswald believes there is a condition of thyroid insufficiency because of the scant colloid and relatively small amount of iodine holding secretion. Marine sums up the problem of the pathology and medicinal therapy based thereon as follows: "(1) Neither specific nor constant anatomic changes in the thyroid of exophthalmic goiter have as yet been demonstrated. (2) The iodine content, the storage of iodine in the gland and the involution of active hyperplasia by the use of iodine are, so far as is at present known, identical with those iodine relations common to other clinical relations. (3) The thyroid of exophthalmic goiter has no different pharmacological action on animals, or therapeutic action on patients with exophthalmic goiter than thyroid preparations of other clinical associations with like iodine contents." The bulk of authorities appear to disagree in their therapies, each citing some existing pathological condition as evidence for the special treatment advocated. Simple hormone therapy has forceful advocates (Mackenzie, Solis Cohen, and others); Kocher reports good results with iodides; Rodgers and Beebe are devoted to the iodothyreoglobulin serum; Starr gained results with sodium glycerophosphate, and so on *ad libitum*. The only common ground appears to be rest, since not all agree as to the value of hydrotherapy, or of electrotherapy, or the manner of dietary regulation.

3. The relative constancy of emotionalism, clinically enlarged thyroid and thymus, and anemia, especially when associated, as they have been in 54 per cent. (24) of these cases, with the tall, slender, willowy type of individual, suggest to the author a clinical picture perhaps best expressed as a "pathologically persistent puberty."

It is possible that there exists an etiological significance in the resemblance between the physiological picture of puberty and the symptom syndrome of systemic goiter.

Puberty, as is well known, is characterized by emotionalism, and a physiologically enlarged or hyperplastic thyroid is not uncommon. Seitz states: "The thyroid gland, in which a congestive and parenchymatous swelling occurs before or during puberty, causing an increase in the organ of 15 per cent. and at the time of menstruation frequently 60 per cent. (Fischer, Freund), has also a decided influence upon bony growth." Jones and Grawitz have shown that the blood at puberty has a relatively small hemoglobin content, and Bayer is authority for the fact of a normally increased leucocyte count at that time. Seitz further states "In the circulatory system disturbances frequently arise at puberty in the form of a cardiac palpitation, sensations of pressure, vertigo, syncope, and shortness of breath. Only when alcohol, nicotine, kidney disease and over-exertion can be excluded as causes, is a direct connection with puberty to be considered. . . . A complete disappearance of cardiac symptoms generally follows the completion of puberty, by virtue of a readjustment of the equilibrium." Gibson, in an address to the British Medical Association, cites an interesting case of the effect of thyroid treatment upon growth. The eighteen-year-old son of a medical man, anxious to enter Woolwich, was one inch short of five feet. His only opportunity to achieve his desired end was six months away. By thyroid feeding he grew seven inches in the six months, and the fact that he attained one of the highest places in the entrance examinations, proves, in Dr. Gibson's opinion, that he was not intellectually injured by the treatment.

It is of passing interest to notice that nitrogen metabolism is increased during puberty and that the basic principle of the thyroid treatment of obesity is the fact that physiologically thyroid causes a destructive metabolism of fat and proteins with a consequent diuresis and loss of weight.

Kocher has suggested that an increased metabolism in the nervous system, such as might be produced by sudden or prolonged nervous exhaustion, brings toxic substances through the circulation to the thyroid gland, and so gives rise to irritation and reaction, causing increased activity of the parenchyma.

Bradford claims that the fact that the thyroid gland in Graves' disease has "a microscopic structure analogous to that seen experimentally when a fragment of the gland is left and undergoes enlargement, has suggested to some observers that the thyroid in exophthalmic goiter is not primary but secondary and arises in response to some need of the economy."

Seitz states, "The thyroid gland in puberty not infrequently shows a strumous degeneration in addition to the temporary or periodic congestive tumefaction which has been noted. This is sometimes noticed in earliest childhood on the basis of inherited predisposition, but is most commonly

observed in the fourteenth or fifteenth year, or in the two following years. It is more frequent in females in whom this gland is from the beginning more developed (Demme). While the physiological congestion is transitory in puberty, mechanical causes at this time may give rise to a chronic congestion." If mechanical causes may produce such a chronic physiological congestion, may not nervous exhaustion do likewise?

Mackenzie mentions the coincidence that, "occasionally Graves' disease in a well marked form, rapidly follows a severe or sudden shock to the nervous system, suggesting that the starting point of the disease may be a derangement of the emotional nervous system, and that with this there is sooner or later associated an altered or perverted condition of the thyroid gland, which serves to keep up many of the characteristic symptoms." He further states that "the assumption that there is a derangement of the emotional nervous system would account for most of the symptoms, but not for the enlargement and overactivity of the thyroid, nor for the persistence and hypertrophy of the thymus." He also claims "the persistence and enlargement of the thymus is certainly a very frequent, if not constant, feature of the disease. . . . Possibly every case in which there is a thymus persisting into adult life is one of potential or latent Graves' disease."

In the light of (1) such parallelisms in the picture of pubertal physiological balance and hyperthyroid symptoms and (2) the general admission of most authorities, that shock is an etiological factor, and the history of pubertal shock in 100 per cent. of the present series of cases, the author would suggest as a possible theory in the etiology of systemic goiter, that it is a pathological syndrome, secondary to a profound disturbance of the physiological pubertal balance by exhaustion of the nervous system either rapidly by strong emotions (such as fear, grief, and the like), or more slowly by overstrain through long sustained effort to gratify ambition (intellectual or physical).

The occasional cases of hyperthyroidism recorded in children under the extreme low variation of normal pubertal age (which the author believes is accepted as seven years), may be due to some similar condition which must account for the equally occasional cases of menstruatio præcox and other abnormalities of infantile sexual maturity.

The fact that so many systemic goiter cases are not recognized—or, as some claim, do not appear—until the third, fourth, or even fifth decade of life, does not, in the author's opinion, disprove the above theory, since all authorities admit that hyperthyroidism is frequently masked for years or misdiagnosed as neurasthenia, hysteria, chronic laryngitis, etc., prior to the appearance of the exophthalmos and the marked thyroid enlargement.

If the above etiological theory will bear dissection and proof, it will serve to explain in large measure why so many widely different types of therapy meet with similar successes and failures, dependent largely, if not entirely, on the extent to which rest as a therapeutic measure is carried and enforced as an accompaniment.

In closing, a word should be said as to the kind of rest necessary in reestablishing the normal physiological balance to a systemic goiter patient. Rest, if both physical and mental, affords unhampered opportunity to the *vis medicatrix naturæ* to restore the physiological balance and produce a cure. In such a regimen, drugs, serums, hormones, and other therapies take their proper places, as crutches, prescribed to sustain *pro tem.* some crippled portion of the organism and should therefore be given symptomatically and not as remedies for the hyperthyroidism *per se.* Rest, if properly enforced, requires considerable of the physician's time and personal attention, because only a very limited number of patients—and perhaps fewer physicians—know *how to rest.* The art of muscular relaxation and passive innervation of the muscles is a difficult one to acquire, and a still more difficult one to teach a "nervous patient," whose whole personality is an expression of active innervation and of muscular tension, and this kind of rest must be minutely taught to a systemic goiter case. In America, and especially in the City of New York, it is more difficult still to teach patients—or physicians—the art of mental relaxation, and this too is an essential lesson for a hyperthyroid case. However, it is not only to our systemic goiter cases, and to our neuropaths generally, but also to our municipal population as a whole, that we need to teach and ourselves to learn the meaning of the German word "gemütlichkeit," or, if a very free translation be allowed, the art and science of contented, rational living.

101 West Eightieth Street.

A NEW METHOD OF INCREASING THE EFFICIENCY OF VACCINES AND OF PRODUCING ANTISERA.

By J. SHERMAN WIGHT, B.S., M.D.,

BROOKLYN, N. Y.

ASSOCIATE VISITING SURGEON TO THE LONG ISLAND COLLEGE HOSPITAL.

THE matter here presented concerns a new method for the production of specific antisera to be used in the treatment of bacterial infections. It involves the problem of bacterial immunity. There are certain primal principles governing bacterial immunity which are recognized as established by all authoritative workers in this field. Such of these as are germain to the subject in hand are herewith stated.

The production of active immunity and a protective serum does not always follow the invasion by bacteria of a susceptible animal. When such an invasion takes place the factors at work can be definitely divided into two groups: (1) Factors relating to the invading bacteria. (2) Factors relating to the defensive mechanism of the animal invaded.

1. Factors relating to the invading bacteria. These are toxins. The toxins produced by bacteria are of two kinds: (*a*) Toxins produced exterior to the bacteria in the tissues and fluids in which the bacteria grow. It is now generally thought that these toxins are formed by parenteral digestion of the proteins in the body tissues by bacterial products. These toxins are properly called exotoxins. Their formation in the invaded animal is accompanied by an elevated temperature. They give rise to the production of antitoxins by the animal body.

(*b*) Toxins produced and contained within the bacterial cell. These toxins are firmly united with the bacterial protoplasm and are only freed therefrom when the bacterial cell is broken down and its

protoplasm disintegrated. These toxins when liberated in the animal are highly diffusible and produce many of the clinical phenomena caused by alkaloidal, vegetable, and mineral poisons. They are properly called endotoxins. They do not give rise to the production of antitoxins in the animal body.

Different species of bacteria vary greatly in their content of endotoxin. All pathogenic bacteria probably contain some endotoxin; most pathogenic bacteria contain a good amount of endotoxin; a few species contain an excessive amount.

From a consideration of these two classes of toxins it is evident that the invaded animal may suffer death from one of three causes: (1) Excessive breaking down of the bacterial cell within the animal body freeing the endotoxin and causing death with rapid fall of temperature, convulsions, and symptoms of collapse. (2) Excessive production of exotoxin, rise of temperature and death with the usual clinical manifestations of high temperature. (3) A combination of (1) and (2).

II. Factors relating to the defensive mechanism of the animal invaded. In response to bacterial invasion, the defensive mechanism of the animal invaded produces a variety of defensive or antiproducts. These products are found in the blood serum or body fluids or contained within the leucocytes. Their primary origin is probably in the leucocytes. These products are present in small amount in the normal animal, but are only increased in amount as the result of bacterial invasion. For the purpose of the present discussion the following antiproducts need special consideration.

Bacteriolytic Products.—These products are directed against the integrity of the bacterial cell, that is, they break down the bacterial cell and disintegrate its protoplasm (parenteral digestion), thus freeing the endotoxin united thereto. For such bacteriolytic action the combined action of two products is necessary: (1) Immune body or amboceptor. (2) Complement.

Amboceptor is present only in small quantity in the normal animal. It is increased in amount in the invaded animal. It is specific, both in normal and invaded animal serum; that is, each species of bacteria has its own amboceptor by which alone it is acted upon. Amboceptor is thermostable, withstanding a temperature of 56° C. The amount of complement in normal and invaded animal sera is always the same. It is non-specific. It is thermolabile, being destroyed by a temperature of 56° C.

Antitoxin.—This product is operative only against the exotoxin. It "anchors" the exotoxin molecule, according to Ehrlich, and thus prevents the toxin molecule from uniting with and damaging other proteins. It is specific. It is thermostable to a temperature of 56° C. It is produced only in the presence of exotoxin.

If we now consider the various antisera which have been produced for the treatment of animal bacterial invasion, we find that they may be classed under two divisions: (1) So-called immune sera. (2) Antitoxic sera.

1. Immune Sera.—These are sera which will protect an animal from invasion with many times the lethal dose of a given bacterium. As to what is required in such a serum to protect the animal will depend, of course, on the endotoxic power of the invading bacterium. If the invading bacterium has no endotoxic power, an immune serum which is simply bacteriolytic will amply protect the invaded animal, for such a serum upon inoculation will destroy all the invading bacteria. If, however, the invading bacteria are endotoxic to any degree the inoculation of a simple bacteriolytic serum will be disastrous to the invaded animal, as it will break down rapidly the invading bacteria, thus freeing the bacterial endotoxin and killing the animal by endotoxemia.

From these considerations it is seen that a bacteriolytic serum may be made powerless by heating to 56° C. This destroys the complement and the serum is inactivated. By adding normal animal serum to the inactivated serum the latter is reactivated. Experimental work *in vitro* has shown that for the highest bacteriolytic action certain quantitative relations between amboceptor and complement are necessary. If to a given amount of complement a small amount of amboceptor is added so that the bacteriolytic action is low, this may be increased by increasing the amount of amboceptor. If now amboceptor is added until the maximum bacteriolytic action is obtained, any further addition of amboceptor reduces the bacteriolytic action; that is, any change in the quantitative relation of amboceptor and complement is followed by a decrease in the bacteriolytic action, and such a decrease holds true whether amboceptor is proportionately diminished or increased to complement.

Opsonins.—These are products which act on the protoplasm of the bacterial cell and render it more susceptible of ingestion and digestion by the leucocytes. They are present in small amount in the normal animal serum and are increased in amount in the invaded animal serum. They are specific in both normal and invaded animal serum. They are generally thermostable, except normal opsonins. They are produced in increased amount only as a result of the presence of the bacterial cell. In proportion as the invading bacteria are endotoxic an immune serum must contain an abundant supply of opsonins in order to give protection. Such a serum through the action of its opsonins will cause the bacteria to be taken up and digested by the leucocytes and prevent endotoxemia. Immune sera are therefore operative directly against the bacterial cell, breaking it up and causing it to be taken up by the leucocytes in which it is digested and its endotoxic products rendered harmless. The test of the power of any immune serum is the number of bacteria against which such a serum will protect the animal body when bacteria and serum are simultaneously injected.

2. Antitoxic Sera.—These sera are operative only against the exotoxin which arises from bacterial growth. Their protective power may be demonstrated *in vitro* by mixing suitable quantities of homologous, antitoxic sera and toxin, or *in vivo* by their inoculation into a susceptible animal which has been inoculated with the homologous toxin, or by inoculating a susceptible animal with the bacterial species which produces the homologous toxin and allowing such bacteria to grow in the animal and produce toxin. Antitoxic sera are specific and cannot be inactivated by heating to 56° C.

Bacteriological examinations of human beings who have recovered from bacterial infections show that when clinical recovery from bacterial infection has taken place the bacteria still remain alive in the body for a variable period. This period is from a few days or a week to many years, sometimes throughout the life of an individual. This is well known to occur after recovery from tuberculosis, typhoid fever, pneumonia, and diphtheria.

It is now necessary to state the theory that was followed in the work here presented. This theory relates to the changes in the defensive mechanism of the animal from the time that the inoculation takes place to the time infection is established. When bacteria such as those of tuberculosis, pneumonia, and typhoid fever gain entrance into the animal body through its open passages they are outside of the body so far as the body cells proper are concerned. Hence, in these locations the invading bacteria stimulate in no way the protective mechanism of the invaded animal. If the bacteria meet favorable conditions for growth in these locations they multiply and then begin to gain entrance into the blood stream. When this occurs the protective mechanism of the invaded animal is established and specific amboceptor is increased in amount, making the blood plasma more bacteriolytic. In this manner the first bacteria which gain entrance into the blood stream are destroyed. There is, however, a continual entrance of more bacteria from the focus in the open body passages. As this process continues the blood plasma increases in bacteriolytic value. If the supply of bacteria from the open passages is sufficient a maximum bacteriolytic value of the plasma is eventually reached. Now, if the supply of bacteria still holds good, any further introduction of bacteria into the body tissues proper increases amboceptor past the optimum for bacteriolytic action, and just as soon as this occurs the bacteriolytic value of the plasma decreases. With the further introduction of bacteria a still further decrease in bacteriolytic value takes place. During this time the bacteria become herded in the various tissues of the body where they have been carried in the blood stream; here they are more free from attack by the bacteriolytic substances in the blood stream and multiply and produce their exotoxins. The fate of the bacteria still in the blood stream as well as those bacteria which pass back into the stream from the herds, is determined by the bacteriolytic value of the plasma and the leucocytic digestion which is now being stimulated by the opsonins which have become increased in amount. As long as there are bacteria in the blood, the herding process continues. The clinical course of the case is determined by what takes place in the herds influenced of course, to a certain extent, by the action of the toxin united with the bacterial protoplasm and freed by parenteral digestion.

The term infection is restricted in this discussion to mean that state in which bacteria have gained a foothold in the animal body, are multiplying and producing their exotoxins with a rise in temperature and the attending pathological lesions. When, therefore, infection has taken place there is a condition in which the bacteria are growing in the infected animal and producing toxin. When this occurs the infected animal brings into play a new defensive factor, namely, antitoxin. We then have in operation against the infecting bacteria, bacteriolytic bodies, opsonins, and antitoxin. At this stage there does not seem to be any reasonable doubt that the mechanism for the production of antitoxin plays a chief part while the forces for the disposal of the bacterial bodies take a secondary rôle. This is forced upon us by the results of animal experimentation. Animals that have recovered from infection with known bacteria show the presence of these bacteria with capacity for growth and exotoxin production. The clinical improvement dates from the moment an antitoxic immunity is established, and so long as such an immunity is maintained the presence of bacteria in the body is harmless. Such an animal takes its time and slowly rids its body of the bacteria with immunity to itself. The value of antisera bears out these contentions. Immune sera are relatively inefficient in the treatment of animals running a course of infection. None have ever been produced which have acted with regularity, while, on the other hand, antitoxic sera act with uniform regularity and success.

It has been universally recognized that antitoxic sera are the most efficient agents for the treatment of bacterial infection. Except, however, in the cases of diphtheria and tetanus it has been impossible to obtain such sera. This is because for the production of antitoxic sera toxin in hand is a necessity and only from the diphtheria and tetanus bacilli has it been possible to obtain such toxin in sufficient quantities for this purpose.

If the blood cells of an infected animal produce the specific bodies, these substances are present in the serum in varying amounts, according to the stage of the disease and their release from these cells. In order to meet a bacterial invasion through this protective mechanism, these substances must not only be produced but they must not remain locked up in the cells. Their release may be fatally delayed. In fact, an earlier release in many cases would hasten recovery. The serum from an infected animal is of no value as an antiserum when it meets only its own demand for specific substances. It must contain a great excess to be a valuable biological product.

The problem that presents itself is how to obtain a supply of specific substances in serum rich enough to make a valuable product. We believe the solution lies with the serum of a strong young infected animal operating a powerful protective mechanism that has had his blood cells broken down at the height of their efficiency. We must find a way of breaking down the cells *in vivo* since nature stops short of the wholesale destruction required. We believe this can be accomplished with sodium hydroxide.

The remarkable results of the intravenous injection of sodium hydroxide in cases of infection, hemophilia, anemia, and cancer, have shown its use to be safe; they seem to the writer to be due to the release of specific bodies through the breaking up of the blood cells and have led him to make a series of animal experiments to prove its action.

Sodium hydroxide was injected into the tissues and veins of normal rabbits and guinea-pigs in the first series of experiments. There was a loss in the total number of leucocytes in the first five hours. Then the total leucocytes and polynuclears increased in number till the end of twenty-four hours, the coagulability of the blood was increased, and normoblasts appeared. At the end of six hours the leucocytes, especially the polynuclears, began to break down and this reached a maximum in twenty-four hours. Repeating the sodium hydroxide renewed these phenomena. The serum from these animals and normal serum were titrated and both were 1.75 alkaline.

The serum from these animals was diluted and one loopful of twenty-four-hour culture of bacteria added to each dilution and incubated for twenty-four hours. One loopful of twenty-four-hour culture of bacteria was added to normal serum in the same dilutions and incubated for twenty-

four hours for comparison with the previous set. In the first set the highest dilution showed the least growth. In the last set there was no difference in the growth in any of the dilutions and they all showed more growth than the highest dilution of the first set. The undiluted sera used in these two sets were injected into the peritoneum of normal animals and produced no effect.

The second series of experiments was performed on susceptible animals injected with pyocyaneus. The control animals had a rise in temperature in the first six hours, some got well in twenty-four hours, and some died of endotoxemia in from twelve to forty-eight hours. It was found that when normal serum was injected into the peritoneum at the same time with the pyocyaneus, the reaction of the animal did not change, but when the serum from the animal that had been treated with sodium hydroxide was injected into the peritoneum at the same time with the pyocyaneus, the temperature fell and he showed evidences of endotoxemia; but when this same serum was injected after the animal's temperature had risen, the temperature stayed up or rose higher and he ran a course of infection with fever for several days, while normal serum injected into the peritoneum of an animal after his temperature had risen, depressed the temperature so that he showed evidences of endotoxemia. Heating the normal serum destroyed this action. Heating the serum from the animal that had been treated with sodium hydroxide increased its effect.

It would appear from these experiments that the serum from the normal animal contained a very little immune body with complement and that sodium hydroxide increased the amount of immune body in the serum. The results of the foregoing experiments are readily explained by bacteriolysis, especially the endotoxemia when normal serum was given after the temperature had risen following the injection of pyocyaneus.

The third series of experiments were performed on susceptible animals inoculated with pyocyaneus. They were injected with sodium hydroxide. A nonlethal dose caused death when sodium hydroxide was given at the time of the inoculation. A nonlethal dose infected an animal only when sodium hydroxide was given several hours after the inoculation. An animal was saved from a lethal dose of pyocyaneus when sodium hydroxide was given several hours after the inoculation. Animals that had been infected were given a large dose of sodium hydroxide and then killed and the serum drawn off to be used in a fourth series of experiments. One of these products was bacteriolytic and another contained antitoxin. The others were immune sera.

It must be remembered that we are operating with endotoxic bacteria and susceptible animals. These bacteria are broken up by parenteral digestion freeing the toxin. The animal will recover and get rid of the invader if the toxin liberated is small in amount, otherwise he will die of endotoxemia.

In this series the animal that received the bacteriolytic serum heated at the same time he was inoculated with pyocyaneus, reactivated it with his own serum and died sooner than the control. The animal that received this same serum heated several hours after his inoculation lived and became infected. This last animal had his own antibody added to that in the bacteriolytic serum, making an excess over what was present in the animal that died and he also had more bacteria, so would also have died of endotoxemia if bacteriolysis had not been lessened by the antibody being carried over the optimum. The immune serum was given heated at the time of inoculation with a lethal dose of bacteria to an animal and he was saved.

In the third series of experiments the serum becomes gradually more bacteriolytic when sodium hydroxide is given at the time of inoculation with bacteria, as the antibody is freed from the cells as fast as it is formed and causes endotoxemia; but when it is given several hours after the inoculation a large amount of antibody has been stored up in the cells, is freed at once in the serum, carries it over the optimum, and lessens bacteriolysis so the animal is saved. The optimum point is delicately balanced.

We believe that these four series of experiments established a fundamental principle in the action of sodium hydroxide on the blood cells, and taking this as a point of departure an attempt was made to produce multiple antisera from mixed sputa. Sodium hydroxide was used to aid in the sensitizing of animal blood cells with bacteria and to hasten antitoxic immunity.

These experiments were performed on animals injected with a mixed sputum from cases of pulmonary tuberculosis and pneumonia. All the tuberculous animals that were treated with sodium hydroxide outlived the controls by many weeks. One animal that had a tuberculous ulcer on the side had lost five ounces, had a temperature of 104°, and was going down rapidly. He was given sodium hydroxide on the same day that the control died, his temperature dropped to normal and he improved, the ulcer began to heal, and he gained weight. In a month he had gained back his original weight and the ulcer was entirely healed.

A series of animals were injected with mixed tuberculous sputum and treated daily thereafter with sodium hydroxide. They ran early temperatures, due to mixed infection, from which they recovered, and about the twenty-first day developed tuberculosis. These were carried along for about two weeks and when their temperatures were down they were given very large doses of sodium hydroxide and killed to get their serum. This was injected into tuberculous animals and promptly brought the temperature to normal and it stayed normal. The serum was obtained from rabbits and injected into guinea-pigs, and the same sputum was used to infect both animals, so that the product was a multiple antiserum, specific for that particular mixed infection. When it was used for the mixed infection of another sputum it did not work as well.

A series of experiments was performed with a mixed sputum from cases of pneumonia. Animals were injected with this mixed sputum and treated with sodium hydroxide; all the animals thus carefully treated developed pneumonia in two days to a week and when autopsied the lung was found consolidated. All the controls died except those that had a small enough dose given to them; these prompty got well without pneumonia. It was necessary to use a small dose of bacteria that the animal could take care of alone in order to give him pneumonia with sodium hydroxide. This partially immunized him and the bacteria were herded in the lungs. It was impossible to give the animals pneumonia without sodium hydroxide, except by the method of Wadsworth. One of the pneumonia animals got well on the twenty-sixth day under sodium hydroxide injections. The serum was taken from

these animals with pneumonia after the cells had been broken down with sodium hydroxide and it was injected into other pneumonia animals during the high fever when the temperature promptly dropped to normal but did not stay there. This was a specific multiple antiserum, but as rabbits were the only animals used it was not powerful enough to produce permanent antitoxic immunity.

When all the preceding facts are correlated it appears to us that our premise has been proved, that sodium hydroxide injected into the animal system increases the number of leucocytes, then breaks down the blood cells and releases the specific bodies they contain.

Reasoning from the results of our animal experiments we further conclude that bacteria sensitize animal cells. The toxin breaks down the cells. This frees all the protective substances they contain. In a chronic disease the cells contain its specific bodies, but do not give them up in sufficient quantity. The acute attack of a different infection will, however, benefit the chronic disease, since its specific bodies are released with the new specific substances but are seldom enough to cure. This explains the increase of specific ferments by Coley's fluid. It is doubtful if defensive products exist in the body until bacteria have sensitized the cells.

Vaccines sensitize animal cells and stimulate the production of protective bodies. These do not always appear in the serum, which makes their action uncertain, unless combined with sodium hydroxide. Vaccines should be used to prevent disease or to stimulate the blood cells that fail to respond to bacteria that have long been present in the body tissues, but never during the active stage of infection, as they do harm by adding foreign waste material, unnecessarily sensitizing the cells, and increasing the danger of endotoxemia. What holds true actively for vaccines is true passively of immune sera. The use of specific multiple antisera must be continued until the system can get its own protection under way, since they do not rid it of the invader.

An animal that has a powerful protective mechanism should take care of itself, but would be protected sooner with sodium hydroxide and lessen the chance of exhaustion. An animal that has its protective mechanism weakened will be saved by a powerful antiserum, and an animal that has its protective mechanism exhausted will die anyway. In pneumonia the bacteria are herded in the lungs from the circulation and not the air passages.

I wish to acknowledge the aid given me in this work by Dr. H. A. Higley.

A SIMPLE SYRINGE METHOD FOR THE TRANSFUSION OF CITRATED BLOOD IN CHILDREN.

By ABRAHAM ZINGHER, M.D.,

NEW YORK.

(From the Research Laboratory and the Willard Parker Hospital, Department of Health, New York City.)

The purpose of this paper is to present a simple method for the transfusion of citrated blood in young children. Transfusion has often been strongly indicated in a variety of medical and surgical conditions in these children, but the necessity for special skill in its performance, and the frequency of failure, have greatly limited its use.

The use of citrated blood in human transfusions was first practised in 1914 by Hustin, who injected in one case a mixture of citrated blood and glucose. Citrated blood in human transfusions was not used again, however, until R. Weil, in December, 1914, recommended the use of 1 per cent. sodium citrate. R. Lewisohn found that 0.2 per cent. sodium citrate will keep the blood fluid, and used that concentration successfully in a few human transfusions at Mt. Sinai Hospital. The method he employed for obtaining and citrating the blood consisted in allowing it to run from the vein through an ordinary cannula into a glass jar containing the proper amount of sodium citrate. The blood was then poured into an ordinary glass funnel and the usual intravenous infusion made. Frequently there is difficulty in obtaining the blood from the donor in this way on account of clotting from the slow flow of blood through the cannula. In the method described below the requisite amount of blood can be rapidly obtained, citrated in several small containers, and easily reinjected even into the small veins of young infants. The main part of the outfit consists of two Record syringes, two suitable needles and some sterile 10 per cent. solution of sodium citrate. In a series of experiments we were able to corroborate the statement that 0.2 per cent. of sodium citrate will keep human blood fluid, whereas 0.1 per cent. failed to prevent clotting. As an additional safety margin 0.33 per cent. is recommended.

It is interesting to note that R. Weil has injected as much as 5 grams of sodium citrate intravenously into adults, and the only effect noticeable was a transient polyuria. He also made the rather important observation that the sodium citrate temporarily hastened rather than delayed the coagulation of the blood.

Twelve transfusions were performed by us successfully on small children, eleven at the Willard Parker Hospital on the service of Dr. Louis Fischer, and one on a seven-weeks-old private patient of his. The median-cephalic vein in this infant, though very small, was readily exposed by means of a small incision in the skin, and the transfusion completed without difficulty.

The following technique is recommended:

Donor.—A suitable donor free from syphilis and tuberculosis is chosen. For small children one of the parents or some close relative will be found most suitable. The serum of the donor should not agglutinate or hemolyze the patient's red blood cells, or *vice versa*. This is conveniently determined by the method of Ottenberg and Epstein.

Instruments and Apparatus.—(*a*) One 30 c.c. and one 10 c.c. improved Record syringe.

(*b*) A platin-iridium or steel needle, 1½ inches

long, No. 18 B. & S. gauge, with which the blood is obtained from the donor.

(*c*) A Goldenberg salvarsan needle (George Tiemann & Co.) for transfusing the blood into the patient.

(*d*) 6-12 sterilized wide-mouthed bottles, in which the blood is collected from the donor.

(*e*) A number of sterile beakers or ordinary tumblers.

(*f*) A 10 per cent. and a 1 per cent. sterile solution of sodium citrate.

(*g*) A piece of rubber tubing and artery forceps as a tourniquet.

Obtaining the Blood from the Donor.—Into each of several 100 c.c. bottles we first introduce 2.5 c.c. of the 10 per cent. solution of sodium citrate. In a glass beaker some 1 per cent. solution of the citrate is kept ready for rinsing out the syringe.

The donor should be placed in a recumbent position and the tourniquet applied to the arm. The platinum needle, attached to the larger Record syringe, is now inserted into the tense median-cephalic vein, and a syringeful of blood quickly aspirated. An assistant now fixes the needle, while the operator quickly detaches the syringe and emp-

Goldenberg salvarsan needle.

ties it into one of the 100 c.c. bottles. During this interval the assistant keeps the needle free of blood by attaching the smaller Record syringe and injecting a few drops of the 1 per cent. solution of sodium citrate. If two large Record syringes are kept on hand, the aspiration of the blood can become almost continuous. Experience has taught us, however, that even with a single syringe a large quantity of blood can be obtained within a few minutes. There is a decided advantage, also, in the intermittent withdrawal of blood, as it allows the donor's circulation to accommodate itself to the fairly rapid depletion, and avoids a sudden cerebral anemia.

Several syringefuls of blood can be readily obtained before it is necessary to rinse the syringe out with the 1 per cent. sodium citrate. Seventy-five c.c. of blood are put into each 100 c.c. bottle, making the final dilution of sodium citrate 0.33 per cent. It is important that with each addition of blood the entire contents be rapidly shaken, in order that the citrate may come into intimate contact with each amount of blood added.

Within ten minutes from 8 to 16 ounces of blood, if needed, can thus be obtained, and is ready to be transfused into the patient.

Transfusion of the Blood.—The blood is aspirated from the bottles by means of a pipette and is collected into a large beaker, or ordinary sterile glass tumbler. It is kept at body temperature by partly immersing the container in warm water. The top of the beaker is covered with a pad of sterile gauze. The best vein for the injection of blood is usually the median-basilic or the external jugular. In older children the salvarsan needle can be inserted through the skin directly into the vein. In very young children, and especially in infants, it is preferable, and even necessary to expose the vein by a small incision, although occasionally one may be able to enter the external jugular vein without an incision. By exposing the vein, however, we are certain that the needle used for the transfusion is properly entering the vein, where it can be safely secured. A catgut or silk ligature is applied to the distal part of the vein; a similar ligature is slipped under the proximal part, but is not tied.

The large Record syringe which has been resterilized is now filled with blood from the beaker. If there is any tendency for the red cells to settle, the blood may be rapidly stirred with the end of the syringe. The Goldberg salvarsan needle is attached to the syringe, and carefully passed into the lumen of the vein, proximal to the tied ligature. This ligature serves to steady the vein, while the needle is being inserted. If care is taken, one can be successful even with the very small veins of young infants. The presence of the needle within the lumen of the vein is tested by first injecting a few drops of blood. If there is no leakage the assistant ties the upper ligature around vein and needle, and thus secures the latter in place. The blood is now slowly injected. As soon as the syringe is emptied, the assistant firmly fixes the needle, while the operator detaches the syringe and refills it with blood. The transfusion is continued until the required amount of blood has been injected.

It is important to be careful not to overburden the patient's circulation with a relatively large amount of blood, and it is therefore advisable not to inject more than 1 to 2½ ounces of blood in infants up to six months of age; 3 to 4 ounces up to one year, and 4 to 6 ounces up to two or three years of age. If necessary, the transfusion may be repeated at intervals of two to three weeks.

After finishing the transfusion, the needle is removed while the proximal ligature is firmly tied. The very slight wound is cleaned with sterile saline and the edges approximated with a strip of sterile adhesive plaster.

Where one desires to use non-citrated blood, the technique can be followed along very similar lines. Two assistants are needed. After securing the salvarsan needle in the patient's vein, we aspirate with a 20 c.c. Record syringe a syringeful of blood from the donor, detach the syringe and promptly inject the contents into the patient's vein. The needles in both donor and patient are kept free of blood by the assistants, who attach small (5 c.c.) Record syringes, filled with sterile normal saline and inject a few drops of the solution. The syringe used for the transfusion of blood is rinsed out with normal saline each time. If two syringes are used, the transfusion becomes almost continuous.

The ease and simplicity of the method would recommend its use in a variety of surgical and medical conditions. The large number of surgical indications need hardly be enumerated. The acute, subacute and chronic anemias, the hemorrhages in hemophilia and purpura, in jaundice, from gastric and duodenal ulcers, typhoid ulcers, etc., will readily suggest themselves. In the treatment of chronic primary anemias, as well as in marasmic and anemic children, successive small transfusions are often considered beneficial and may at times be life-saving. In the treatment of toxemias, like that of scarlet fever, transfusion is indicated, if a suitable convalescent donor can be found.

The outlook would be sufficiently hopeful, if a method for the transfusion of blood, which is easily carried out, could be placed in the hands of the general practitioner. The technique of the handling of syringes is easily acquired, and it should, no doubt, be taught to every medical student.

Conclusions.—1. A simple method is here presented for the transfusion of blood in young infants and children with an outfit which consists mainly of two Record syringes, two suitable needles and a sterile solution of sodium citrate.

2. The advantages claimed for the method are its simplicity, the rapidity with which the blood is obtained and citrated in several small containers, the complete control over the rapidity of the injection of the blood and the amount of blood injected, and the applicability of the method, even to very young infants.

I wish to thank Dr. Louis Fischer for the cases referred to me for transfusion. A detailed report will soon appear by Dr. Fischer and the author on the clinical aspect of the cases transfused. I also wish to thank Mr. David Soletsky for valuable assistance during the transfusions.

A NEW BABY BOTTLE.

By Rudolph Duryea Moffett, M.D.,
New York.
Assistant Visiting Physician in the German Hospital and Dispensary, the Dr. A. Jacobi Children's Division; Attending Physician to the Children's Department of the German Hospital Dispensary, Assistant Attending Physician Babies' Hospital Dispensary.

The many varieties of baby bottles which have been used for a number of years have had three common objections, namely; inability of easy cleansing, inaccurate graduation, and wide opening requiring the use of excessively large nipples.

Being impressed with these objections I have

sought to overcome them by (1) having a bottle constructed without a neck, the body of the bottle converging to its opening at the top as per illustration; (2) each bottle being accurately graduated and the lines of the ounces and half-ounces etched on the glass; (3) the body of the bottle, by converging to a small opening, as per illustration, requires only the usual size nipple. This bottle is made by the Kimble-Durand Glass Co., of New York and Chicago, and meets all the above requirements, and demonstrates its superiority over other types of feeding bottles, which have heretofore been so difficult to clean. The illustration shows the shape of the bottle, which is made of very hard glass similar to that used for laboratory purposes, stands great changes of heat and cold, and therefore can be thoroughly sterilized.

Medicolegal Notes.

Hypothetical Questions—Actual Cause of Death.—Upon a trial for uxoricide two distinct theories were urged as to the cause of death. The State urged that it was caused by strangulation; the defense, that it resulted from accidental fall from the porch of the defendant's house. The evidence tending to sustain both theories was almost entirely circumstantial, but there was substantial support for both. Aside from the presence of the defendant at or nearby at the time to the place where death occurred no witness testified to facts immediately connected with it. Upon the theory of the State the death was feloniously caused, and because the defendant was the only one shown to have been in such proximity to the scene as to permit connection with the alleged act, coupled with statements and silence when accused, which were claimed to have the legal effect of admissions, and with evidence upon which was based the claim of the existence of a motive by him, the ultimate question upon which the prosecution relied as demanding a conviction was that the death resulted from strangulation and from wounds made in connection with such act at the hands of the defendant acting wilfully through malice, deliberation, and premeditation with the intent to take his wife's life. Medical witnesses were examined as experts. Shortly after the death an autopsy was held, and the physicians who were present and assisted in it testified in detail as to the condition of the body, the internal organs, and the blood vessels. A hypothetical question was propounded to the several witnesses called by the State to testify as experts, some of whom had not assisted at the autopsy, each being asked as a part of the question whether upon the assumed facts thus stated he would be able to give an opinion as to the cause of death. It was objected that the question called for a conclusion and opinion of the witness as to his own ability to pass upon a matter such as was embraced in the inquiry. The objection was not sustained, it being held that the answer to the question would be merely the statement that the assumed facts were such that to the trained mind they carried knowledge upon which an opinion could be based. The question was quite different from an interrogatory as to whether the witness was in fact qualified to testify as an expert. Nor did it invade the province of the jury, the ultimate question for the jury being whether the death was felonious. It was held that the witnesses were not restricted to stating what was the probable cause of death, but might state what in their opinion was the actual cause of death.—State vs. Hessenius, Iowa Supreme Court, 146 N. W. 58.

Right to Publish Medical Advertisements.—The police power of the state is limited to enactments which have reference to the public health or comfort or the safety or welfare of society, consequently the Colorado Supreme Court holds that Rev. Stat. 1908, Sec. 6068, authorizing the State Board of Medical Examiners when any practitioner causes the publication of any advertisement relative to any disease of the sexual organs, to revoke his license, is unconstitutional, being in violation of Const. U. S., Amend. 14, and Bill of Rights, Art. 2, Sec. 3, prohibiting the deprivation of life, liberty, or property without due process of law, for the right to practice medicine is a valuable right and the statute in question would authorize the revocation of a license for conduct which would not necessarily be immoral or injurious to the public. The statute was also held to be so indefinite as to be invalid; neither it nor dictionaries nor general usage defining the term "diseases of the sexual organs." As the offense of causing the publication of immoral advertisements is a public one the statute is invalid as class legislation, being discriminatory. —Chenoweth vs. State Board of Medical Examiners, Colorado Supreme Court, 141 Pac. 132.

Matters to Which Physician May Testify.—Where the plaintiff in an action for personal injuries alleged to have been sustained by the negligent sudden starting of a street car which she was boarding testified that she suffered a miscarriage in consequence of her injuries, a physician called as a witness for the plaintiff may properly be asked whether he made an examination for any conditions that might result from a miscarriage, the inquiry relating to a subject within the issues of the case.—Powers v. Chicago City Ry. Co., 185 Ill. App. 158.

THE PHYSIOLOGY AND PATHOLOGY OF INFANCY.

APPARENTLY for the first time in the history of medical education, there has been established at the University of Paris a chair of hygiene and clinical medicine of infancy. The first occupant of this chair, A. B. Marfan, in his inaugural address published in the *Presse Médicale*, January 7, 1915, points out how two events more than any other in France at the present time emphasize the importance of the conservation of child life, namely, the diminishing birth-rate and the vast destruction of life incident to the present war. These circumstances impart a special significance to the foundation of a chair of infant hygiene in a university subsidized by the French government.

Infancy has its peculiar problems in physiology and pathology, a correct conception of which problems demands a subdivision of childhood into three stages: the "petite enfance," extending from birth to the end of the first dentition at the age of two and a half years; the "moyenne enfance," extending from this period to the beginning of the second dentition at six or seven years; and the "grand enfance," extending from the sixth or seventh year to the twelfth or sixteenth year. Each of these periods has its own problems, but those of the latter two are mere modifications of those of adult life, while the problems of the "petite enfance" are distinctively different and constitute a separate branch of medicine. There are no English terms which correspond exactly with the French expressions; possibly the same connotation is attached to the terms, infancy, early childhood, and later childhood.

There are three principles underlying the morbid reactions of infancy: (1) an acute disease in an infant previously healthy causes an intense and a diffuse reaction out of all proportion to the benignity and localization of the acute disease, as may be seen in the case of acute inflammation of adenoid growths. (2) An infectious disease occurring in an infant does not remain localized at the point of entrance of the infectious agent: there is a wide extension chiefly by way of the lymphatic apparatus. (3) Chronic diseases in the infant, unlike those of the adult, are characterized by modifications of the general condition rather than by predominantly local changes. The general manifestations are the arrest of growth and weight, a peculiar anemia resembling that of chlorosis, and a morbidly increased activity of the hemolymphatic apparatus, particularly of the bone marrow. It is the last reaction which Marfan regards as the essence of rachitis, or as he terms it, "osteolymphatism."

The retardation in growth and weight seems to be the most conspicuous fact in infantile pathology, but there are associated phenomena which are usually overlooked. One of these is the disappearance of the power to react to acute infections. In an atrophic infant these may arise without fever or nervous manifestations. Even the local signs may be all but wanting, as in the case of bronchopneumonia occurring in an athreptic infant, when careful and prolonged auscultation may be necessary in order to elicit the physical signs.

The older conception of infantile atrophy as a definite clinical entity has given place to one in which the atrophy is regarded as the constitutional reaction to vicious feeding, either insufficient, excessive, or inappropriate; to such chronic infections as syphilis, tuberculosis, and prolonged pyodermatitis; or to a subacute or relapsing bronchopneumonia.

At first glance, some of the observations made by Marfan may appear commonplace or even hackneyed, but on closer examination, one can perceive how the touch of genius, guided by unusual experience, imparts to these observations a new light and a new meaning. It is only by a full realization of the underlying principles of infantile pathology that one can hope to combat the awful mortality at the threshold of life. In these days when politics and science vie with each other in a wholesale slaughter of the flower of manhood, the necessity of conserving the newborn, the heritage and the hope of the race, receives an added importance.

VARIETIES OF PNEUMOCOCCUS AND THEIR RELATION TO LOBAR PNEUMONIA.

IT it now over a year since Dochez and Gillespie showed that pneumococci derived from lobar pneumonia might be divided into four well-defined groups according to their immunological reactions. The first three groups, pneumococcus type I and type II and the *Pneumococcus mucosus*, are made up of individuals that have a definite biological relation to each other; that is to say, each member possesses immunity reactions which are identical with those of the other members of that group. The fourth group is peculiar "in that it seems to consist of a series of independent varieties which do not cross in their immune reactions with members of group I, II, or III, or with each other." Since that publication the work has been continued and extended. In a recent paper (*Jour. Exper. Medicine*, 1915, xxi, 114) Dochez and Avery report the results of their further activity in this direction. In a study of the pneumococci found in the mouths of healthy individuals who had not been exposed to cases of pneumonia they found that, so far as they were able to tell, the organisms belonged to the heterogenous group IV. In persons

who had been exposed to cases of pneumonia, the more virulent types were usually found, corresponding to the type of organisms infecting the case in question. After such exposure the virulent type may persist for a variable length of time, during which period the individual is a true carrier. Examination of the mouths of patients after recovery from an attack of pneumonia showed that within from twelve to ninety days the "virulent type" is replaced by a strain belonging to group IV. "In general, when typical organisms persist for a long time, there is delay in the healing of the lung lesion. If recovery is prompt, as a rule, the virulent types disappear rapidly." The organisms belonging to group IV are of low virulence, being responsible for about twenty per cent. of the cases of pneumonia. The mortality percentage is much lower in this group than in the others.

It is thus apparent that the majority and the more virulent of the cases of pneumonia are caused by a strain of the pneumococcus which is not found in normal mouths, a result which tends to negative the former belief that, under favorable conditions, the pneumococci living in the mouth are enabled to invade the organism and produce the disease. On the contrary, it is much more probable that "the majority of cases of pneumonia are dependent upon either direct or indirect contact with a previous case." Of course the predisposing causes are none the less important. The authors obtained five strains of pneumococcus which were responsible for pneumonia as it occurs in South Africa and found that three of them belonged respectively in groups I, II, and III. The other two, however, were independent strains indicative of new groups which are probably not represented in this country. They suggest that in especially susceptible persons, such as the native negroes, some of the normally non-virulent strains of group IV may acquire virulence and develop into clear cut types. The development of a racial immunity would soon limit the number of new types which might arise.

This work emphasizes in a way not hitherto equaled, the importance of exposure in any consideration of the epidemiology of pneumonia; and it should be remembered always in planning out the treatment of any case of pneumonia, especially in private practice.

TYPHUS FEVER.

The outbreak of the European conflict has again demonstrated that freedom from pestilence is a matter of hygiene and civilization, and that if from any cause there is a retrogression previously dormant disease breaks out with renewed vigor. Very few physicians, other than those engaged in public health work, ever have the chance to see such diseases as plague, yellow fever, cholera, leprosy, the comparatively common smallpox and typhus fever—the diseases quarantinable by the national government. Yet it is quite recently that every one of these conditions prevailed in epidemic proportions, and contributed to the large death rates and short span of life.

Of the quarantinable diseases typhus fever was thought to be particularly rare until the investigations of Anderson and Goldberger of the Hygienic laboratory showed that the disease described as a result of the keen observation of Dr. Nathan Brill of New York was in fact a typhus fever of mild course, and was identical with the type of typhus existent in Mexico. This Brill typhus is found to be confined almost entirely to immigrants from Russia, though in a severer form the disease has been discovered among immigrants arriving from the east.

Typhus has been reported to have broken out with a great deal of severity among some of the belligerents in Europe, and with somewhat of the dread consequences of the typhus of old. With the resumption of immigration, especially from these localities, the introduction of a more severe strain of typhus infection will be a matter to guard against. The mild course of typhus in this country may be due to a possible attenuation of the organism or virus causing the disease, although with the exception of a little preliminary work in the isolation of the specific organism, little is known of either; or it may be due to the better hygienic and social conditions of the people—better at least than in the places where the diseases are endemic. Yet the introduction of a severer strain or the lowered resistance of the victims might be provocative of a very serious epidemic.

With all its epidemicity the disease is yet very preventable, since it is fairly well established that it is transmitted almost solely by the body louse. The proverbial residence of this insect on the vestments of the soldier in the field accounts for the prevalence among military units. Care in the disinfection or destruction of the clothing and linen of patients will prevent spreading to others and to the attendants. The nocturnal character of the body louse must also be borne in mind in relation to transmission of the disease. It has been established by experimentation on monkeys that the organism seems to be filtrable, that the blood contains the virus, and that the body louse is the intermediary host. It should not therefore be difficult to destroy the insect, isolate the patient, and thus prevent the spread of the disease.

Diphtheria Toxin and Blood Pressure.

Of considerable clinical importance is the problem as to what effect the diphtheria toxin has upon the blood pressure. This problem has been studied by H. Zondek (*Zeitschrift für klinische Medizin*, Vol. 81, Nos. 1 and 2), who found that the blood serum of rabbits acutely poisoned by the diphtheria toxin causes a reduction of blood pressure when injected into healthy rabbits. In a parallel set of experiments normal rabbit serum had no such effect. The blood serum of rabbits in which a nephritis has been set up by the injection of uranium or chromium salts, causes a distinct rise in the blood pressure in rabbits in which the blood pressure had been lowered by the diphtheria toxin. The degree of the blood-pressure reducing power of the diphtheria-treated rabbit sera depends upon the length of time to which these sera have been under the influence of the diphtheria toxin. The maximum of this power is reached in ten hours, and at the end of twenty hours there is a marked reduction. The effect of the diphtheria serum upon the blood pressure is

more prolonged if this serum is removed from a rabbit in which a nephritis has been set up. In such an animal the histological changes in the kidney are more pronounced after twenty hours than after ten hours. In all probability a coincident nephritis tends to counteract and to compensate for the blood pressure reducing effect of the diphtheria toxin. The above mentioned experiments have an eminently practical bearing inasmuch as they indicate the need of blood pressure observations as an aid in gauging the intensity of a diphtheritic infection and also as a means of enabling one to suspect an intercurrent nephritis.

Treatment of Gangrenous Wounds with Artificial Gastric Juice

The use of both natural and artificial gastric juice in the treatment of ulcers and suppurative processes is quite old, especially the first named which was applied for this purpose long before the nature of the secretion was understood. During the present war an attempt has been made to introduce the use of an artificial product on a large scale for the treatment of foul gangrenous lesions. Freund of Vienna reported his experience before the Royal Imperial Medical Society of Vienna last December (*Münchener medizinische Wochenschrift*, January 12.) To a 0.1 or 0.2 per cent. solution of hydrochloric acid he adds pepsin to make 2 to 5 per cent. The wound surface may simply be irrigated or dressed with moistened gauze. The solution should not have stood for over 48 hours and cannot be heated above 45° C. (113°F). It may be used twice daily after previous disinfection with hydrogen peroxide. If nerves or vessels have been exposed by the gangrenous process or the traumatism itself, these structures should be protected from the solution by petroleum ointment. At the same meeting Gagstatter stated that he had used the solution in 80 cases, often with astonishing results. The necrotic tissues were promptly removed.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—During the past two months there has been a falling off in contributions to the general fund for Belgian relief from over $300,000 in November to less than $100,000 in February. There is therefore all the more need for generosity on the part of medical men. It cannot be impressed too forcibly on the members of our profession that their colleagues in Belgium need their help even more now than when the subscription lists were first opened. The establishment by the Germans of a "war zone" around Great Britain has deprived the starving Belgians of the supplies formerly sent them from England, so that they must look more than ever to this country for help. There are now three American committees asking aid for the Belgian physicians, the other two being the one appointed by the New York Academy of Medicine and that established by the editor of *American Medicine*, and we would urgently appeal to our readers who have not yet responded to send a donation, no matter how small —or how large—to one or the other of these relief organizations—it matters not which. The objects of each committee are the same and the members of each will rejoice to see its own collection exceeded in amount by its rivals in this great and appealing work of charity. Contributions may be sent to the editor of the Medical Record, or preferably to the treasurer of the committee, Dr. F. F. Simpson, 7048 Jenkins Arcade Building, Pittsburgh, Pa.

The following is from a letter to Dr. Simpson from Dr. J. M. T. Finney of Baltimore: "Madame DePage was in Baltimore for a short time last week. I told her something of the work that the medical men in this country were doing for their confrères in Belgium. She was much interested and most grateful for what had already been done. . . . Her account of conditions in Belgium is pathetically interesting. The needs of her country beggar description. While so much is being done and has already been done by this country, much more must be done in order to save from starvation many hundreds of men, women, and children. I wish it were possible for everyone to hear her account of what the Belgians are doing for themselves and of their gratitude for what is being done for them and, at the same time, get some sort of an appreciation of the magnitude of the need for more and immediate assistance. I feel sure it would result in a more prompt and generous response on the part of the profession than that which has already been made."

The treasurer reports the following contributions received during the week ending March 6, 1915:

Dr. Grace Wolcott, Boston, Mass.	$10.00
Dr. Harold E. Perry, New Bedford, Mass.	10.00
Pittsburgh College of Physicians, Pittsburgh, Pa.	45.00
Dr. Daniel R. Robert, Brooklyn, N. Y.	5.00
Mrs. Charles E. Paddock, Chicago, Ill.	5.00
Dr. Chas. S. Wright, Acting Asst. Surg., U. S. A., Portland, Me.	5.00
Dr. E. C. S. Taliaferro, Norfolk, Va.	30.00
Dr. William H. Wilder, Chicago, Ill.	25.00
The Thunder Bay Medical Society, Ontario, Canada.	25.00
Garland Co., Hot Springs Medical Society, Hot Springs, Ark.	25.00
Dr. J. Shelton Horsley, Richmond, Va.	5.00
Dr. E. F. Dodds, Missoula, Mont.	5.00
Dr. George R. Little, Wichita, Kansas.	25.00
Dr. James A. Jackson, Madison, Wis.	5.00
Total for week ending March 6.	$225.00
Previously reported	4,386.50
Total receipts	$4,611.50
Previously reported disbursements:	
1,625 standard boxes of food at $2.20	$3,575.00
352 standard boxes of food at $2.30	809.60
	$4,384.60
Disbursements week ending March 6, 100 boxes of food at $2.30 per box	230.00
Total disbursements	$4,614.60
Deficit	$3.10

Health of the Canal Zone.—The report of Dr. Charles F. Mason, Chief Health Officer, for December states that the number of deaths among the employees in the Panama Canal Zone was 19, of which 11 were from disease, giving a rate of 3.64 per thousand as compared with 1.61 for the preceding month and 5.24 for December, 1913. There were no deaths from disease among white employees. The diseases causing the largest number of deaths were as follows: Lobar pneumonia, 2; tuberculosis of the lungs, 2. No other diseases caused more than 1 death. The constantly noneffective rate was 10.57, compared with 10.82 for the preceding month and 14.33 for the corresponding month of last year. The total admission rate for malaria, in hospitals and quarters, was 60.95, compared with 69.08 for last month, and the total noneffective rate 1.18, compared with 1.53 for last month, each of these rates being lower than for the same month last year.

Death Rate in New York City.—The number of deaths from all causes reported during the week ending February 27 was 1,518, which is 294 less than for the same week of 1914. The death rate for the first nine weeks of 1915 was 13.91 per thousand of population, as compared with 15.08 during the same period in 1914.

Life Saving in New York State.—The State Charities Aid Association says that a saving of more than 2,000 lives in the State outside of New York City is indicated by the decrease of five points in the death rate, from 15.8 per 1,000 population in 1913 to 15.3 in 1914. These figures are based on the United States Census estimate of population. This was the lowest rate in the history of the State, and the State Department of Health declares that 25,000 persons can be saved from death by improved hygiene in New York State within the next five years.

Deaths from Street Accidents.—According to the report of the National Highways Protective Society, eighteen persons were killed in February by automobiles on the streets of this city, nine of these being children under 17 years of age. During the corresponding month of 1914 eight were killed by automobiles. During the month trolley cars caused the death of five and wagons four, as compared with ten by trolley cars and two by wagons last February. Six persons met their death by automobiles, three by trolley cars, and one by wagon on the streets and highways of New York State, outside of Greater New York, as compared with three by automobiles and four by trolley cars last year. In New Jersey six persons were killed by automobiles and one by trolley car the past month. During the same period twelve persons were killed at highway railroad grade crossings in New York State and six in the State of New Jersey.

American Posture League.—The second annual luncheon of this association will take place at the Hotel Astor on Saturday, March 13, at half-past 1 o'clock. The first annual luncheon was exclusively for the honorary boards of the League, but proved so helpful that this year invitations have been extended to the general membership of the League and to a number of others interested in the movement. The after-luncheon program will set forth the educational, scientific, and welfare aspects of the work of the organization. The president and founder of the league, Miss Jessie H. Bancroft, will preside and will speak on the "History, Plan, and Work of the American Posture League"; other speakers will include Dr. Frederick R. Green of Chicago, first vice-president of the League; Dr. Joel E. Goldthwait, second vice-president, and Dr. E. G. Brackett, both of Boston; Dr. Eliza M. Mosher, Dr. Henry Ling Taylor, secretary, and Dr. S. Josephine Baker of New York. Dr. Percy W. Roberts will present a report of original research conducted by the league; Dr. Anna L. Brown will tell of the national contest on posture being conducted by the Young Women's Christian Association, and Mr. Harry O. Bullock will speak for the Brooklyn Rapid Transit Company, relative to the seats in the new subway cars, which the Posture League designed in cooperation with the construction engineers of the company.

The Medical Society of the State of New York will hold its one hundred and ninth annual meeting in Buffalo, April 27-29. All the sessions, general and sectional, will be held in the 65th Regiment Armory. A restaurant will be conducted in the building, and there will be ample space for commercial and scientific exhibits.

Civil Service Examination.—An examination will be held on April 3 to fill the position of assistant attending surgeon, New York State Hospital for the Care of Crippled and Deformed Children, West Haverstraw. Salary $800 per annum. The appointee will be required to attend the hospital twice a week. No written examination will be given, but candidates will be rated on their age, education, preliminary training, and experience, as determined from the sworn statements in their application, and by inquiries which the commission may make. Applications must be received in the office of the State Civil Service Commission, Albany, N. Y., on or before March 26. No application blanks will be sent out by mail after March 24.

Surgeon-General Gorgas has been promoted to the rank of Major-General in recognition of his work in the sanitation of the Canal Zone.

Dr. Hugo O. Peterson has been appointed city physician in Worcester, Mass.

Dr. Frederick J. Ripley has been reappointed health officer for Brockton, Mass.

Dr. John J. Deacy has been appointed health board physician in Lawrence, Mass.

Dr. W. S. Wheeler has resigned the office of health commissioner of Kansas City, Mo.

Dr. Adelaide Brown of San Francisco has been appointed a member of the California State Board of Health, to succeed Dr. O. Stansbury.

Dr. Horace Grove Deming has been appointed professor of chemistry and chief of the department in the University of the Philippines, filling the vacancy occasioned by the death of Dr. Paul Caspar Freer.

Dr. Andrew Hunter has resigned the position of biochemist, U. S. Public Health Service, in order to accept the chair of pathological chemistry in the University of Toronto.

A Proposed Vaccination Test.—An antivaccinationist in Jersey City has offered to give $2,000 to any charity or medical society under the following conditions: Five of the medical staff of the Jersey City School Board are to vaccinate themselves and after it has taken (if they are not already protected) must submit to inoculation with smallpox virus. If three out of the five do not have smallpox the money will be paid.

Hospital Notes.—An effort is being made by business men in Wall Street to establish a general and emergency hospital on Broad street with an endowment of $1,000,000. An option on four floors of an eight-story building has been secured, with the understanding that the four remaining floors may be used. The hospital will be known as the Broad Street Hospital in the City of New York.

Announcement is made that a new hospital will be built for the medical department of Ya-li (which is Chinese for Yale) College in Chang Sha. Twenty acres of land have been purchased outside the city and on it will be erected the hospital building, a dormitory, a chapel, and four buildings for professors.

By the will of the late Marietta Flower of Chester, Pa., the sum of $5,000 is bequeathed to the Chester Hospital, together with the residuary estate. Also by her death the hospital will come into possession of the entire estate of her brother, amounting to $150,000.

Award of the Samuel D. Gross Prize.—The

Samuel D. Gross Prize of the Philadelphia Academy of Surgery for the year 1915, to the value of $1,500, has been awarded to Dr. John Lawrence Yates of Milwaukee, Wis., for his essay entitled "Surgery in the Treatment of Hodgkin's Disease."

The Campaign Against Rabies.—An important legal decision has just been rendered by Mr. Justice Lehman of the Supreme Court upholding the right of the Department of Health of this city to enact and enforce an ordinance providing for the muzzling of all dogs in the streets and other public places of this city. The department has always insisted, however, that the enforcement of the dog muzzling was only part of the campaign necessary to eradicate rabies from this community. Equally important is the destruction of stray dogs and cats. In this city this work is in the hands of the American Society for the Prevention of Cruelty to Animals. During the year 1914 this society destroyed 18,510 dogs and 49,940 cats, and in 1913, 16,180 dogs and 51,678 cats. The Health Department Bulletin states that there has been a decided falling off in the number of dog-bites in this city during the past six months. Moreover, laboratory examinations indicate also a decrease in the number of rabid animals.

Medical Passengers on "La Touraine."—On the French steamer *Touraine*, which was on fire off the coast of Ireland last Saturday were Dr. and Mrs. J. C. Walker of the American Ambulance Hospital, Paris, and Drs. John S. Irwin, W. G. Braddock, and A. O. Jimenis with ten nurses and an orderly from the French Hospital, New York, who are to establish a military branch at Passy in France. Dr. J. S. Wheelwright of this city, who will have charge of a hospital in France, was also a passenger.

Medical Society Elections.—The Association of Southern Medical Women held its second annual meeting in Richmond, Va., on November 10, electing the following officers: *President,* Dr. Mary E. Lapham, Highlands, N. C.; *Vice-President,* Dr. Mary A. Parson, Washington, D. C.; *Secretary-Treasurer,* Dr. L. Rosa H. Gantt, Spartansburg, S. C.

The Dubuque County (Iowa) Medical Society, at the annual meeting held January 12, elected the following officers: *President,* Dr. I. E. Bigelow; *First Vice-President,* Dr. Lilly Kinnier; *Second Vice-President,* Dr. H. M. Pahlas; *Treasurer,* Dr. L. H. Fritz; *Secretary,* Dr. C. A. McGuire; *Librarian,* Dr. W. P. Slattery; *Delegate to the State Society,* Dr. J. C. Hancock; *Alternate,* Dr. H. G. Langworthy; *Board of Censors,* Drs. J. M. Walker, B. Michel, and W. Becker.

The Winona County (Minn.) Medical Society held its annual meeting in Winona on January 5, and elected the following officers: *President,* Dr. H. C. Bear, St. Charles; *Vice-President,* Dr. B. P. Rosenberry, Winona; *Treasurer,* Dr. W. R. C. Heise, Winona; *Secretary,* Dr. H. F. McGaughey, Winona; *Delegate to the State Society,* Dr. E. S. Muir, Winona; *Alternate,* Dr. E. M. McLaughlin, Winona.

American Association of Anatomists, at its annual meeting, re-elected the following officers: *President,* Professor G. Carl Huber, University of Michigan, Ann Arbor, Mich.; *Vice-President,* Professor F. T. Lewis, Harvard Medical School, Boston, Mass.; *Secretary-Treasurer,* C. R. Stockard, Cornell University Medical College, New York City.

The Philadelphia Medical Club, at a stated meeting held January 15, elected the following officers for the ensuing year: *President,* Dr. McCluney Radcliffe; *First Vice-President,* Dr. Alexander MacAllister; *Second Vice-President,* Dr. William Martin; *Secretary,* Dr. William S. Wray; *Treasurer,* Dr. Lewis H. Adler, Jr.; *Governor,* Dr. George A. Knowles, for a five-year term.

The Northern Medical Association of Philadelphia, at a stated meeting held January 8, elected the following officers for the ensuing year: *President,* Dr. Victor A. Loeb; *Vice-President,* Dr. Moses Behrend; *Secretary,* Dr. Samuel Axilbund; *Treasurer,* Dr. John W. Millick.

The Escambia County (Fla.) Medical Society, at a meeting held January 12, elected the following officers: *President,* Dr. Louis deM. Blocker; *Vice-President,* Dr. W. D. Nobles; *Secretary,* Dr. F. A. Brink; *Treasurer,* Dr. M. A. Lischkoff; *Board of Censors,* Drs. George Kilpatrick, Mallory Kennedy and J. H. Fellows.

The Dinwiddie County (Va.) Medical Society, at its regular meeting held in Petersburg on January 14, elected the following officers: *President,* Dr. E. W. Perkins, Petersburg; *Vice-President,* Dr. H. G. Leigh, Petersburg; *Secretary,* Dr. D. C. Mays, Church Road; *Treasurer,* Dr. A. F. Bagby, Petersburg; *Delegate to State Society,* Dr. J. Gordon Rennie, Petersburg; *Censors,* Drs. R. A. Martin, Petersburg, E. W. Young, McKenney, and G. S. Fultz, Butterworth.

The Thomas County (Ga.) Medical Society, at a special business meeting held in Thomasville, January 21, the following officers were elected: *President,* Dr. J. N. Isler; *Vice-President,* Dr. J. B. Palmer; *Secretary and Treasurer,* Dr. S. L. Cheshire; *Delegate to the State Convention,* Dr. A. D. Little; *Alternate,* Dr. J. N. Isler.

The Stark County (Ohio) Medical Society, at its annual meeting in Canton on January 20, elected the following officers: *President,* Dr. G. W. King, of Alliance; *Secretary and Treasurer,* Dr. L. A. Buchman, of Canton; *Corresponding Secretary,* Dr. G. C. Goudy, of Canton.

The Utah County Medical Society held its annual meeting in Provo on January 13, and elected the following officers: *President,* Dr. Frederick Dunn, Springville; *Vice-President,* Dr. H. G. Merrill, Provo; *Secretary and Treasurer,* Dr. Walter T. Hasler, Provo; *Member Committee on Membership,* Dr. O. E. Grua, Pleasant Grove; *Delegates to the State Society,* Drs. J. W. Aird and A. J. Stewart, Provo, Heber Robinson, American Fork, and J. W. Hagan, Spanish Fork.

The Fresno County (Cal.) Medical Society met on January 5 and elected the following officers: *President,* Dr. J. L. Maupin; *First Vice-President,* Dr. H. J. Craycroft; *Second Vice-President,* Dr. R. M. Jones; *Secretary,* Dr. L. R. Willson; *Assistant Secretary,* Dr. C. D. Sweet; *Delegate to State Society,* Dr. C. O. Mitchell; *Board of Governors,* Drs. G. H. Aiken, D. H. Trowbridge, W. T. Barr, J. R. Walker, and L. R. Willson.

The Venango County (Pa.) Medical Society, at a meeting held at Franklin on January 19, elected the following officers: *President,* George B. Jobson, of Franklin; *Vice-President,* Sydney A. Slater, of Grandview, Oil City; *Secretary,* J. L. Zerbe, of Franklin; *Treasurer,* John F. Davis, of Oil City; *Censor,* J. B. Siggins, of Oil City.

The Elkhorn Valley (Neb.) Medical Society, at a meeting held at Omaha on January 20 and 21, elected the following officers: *President,* Dr. R. D. Davies, Arlington; *Vice-Presidents,* Drs. H. G. Morris, Creston, and H. L. Wells, West Point; *Secretary,* Dr. A. P. Overgaard, Fremont; *Treasurer,* Dr. E. L. Brush, Norfolk. Columbus was chosen as

the place for the next meeting, to be held in midsummer.

Obituary Notes.—Dr. Dwight Reed of Honesdale, Pa., a graduate of the New York University Medical School, New York, in 1848, died at his home on February 21, aged 90 years.

Dr. Malcolm J. Farrish of Sherburn, Minn., a graduate of Trinity Medical College, Toronto, in 1891, died at his home from tuberculosis, on January 22, aged 60 years.

Dr. Francis Hustace of New York, a graduate of the College of Physicians and Surgeons, New York, in 1874, died as the result of an accident on February 17, aged 64 years.

Dr. Albert Samuel Cooke of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1901, who had been serving as a volunteer physician in the military hospital at Valemevo, Servia, is reported to have died there recently. Dr. Cooke was 36 years of age.

Dr. Charles L. Powers of Coffeyville, Kan., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1878, died at his home on February 3, aged 70 years.

Dr. Dudley Sharpe Reynolds of Louisville, Ky., a graduate of the University of Louisville, Medical Department, in 1868, and a member of the American Medical Association, the Kentucky State Medical Association, the Jefferson County Medical Society, and the American Academy of Ophthalmology and Oto-laryngology, died suddenly at his home from angina pectoris, on February 4, aged 72 years.

Dr. Amos Hagar Peirce of Merrimac and West Newbury, Mass., a graduate of the Boston University School of Medicine in 1882, and a member of the American Medical Association, the Massachusetts Medical Society and the Essex District Medical Society, died at his home after a short illness on February 9, aged 56 years.

Dr. William H. Rowe of St. James, Minn., a graduate of the Rush Medical College, Chicago, in 1882, president of the St. James Hospital, a member of the American Medical Association, the Minnesota State Medical Association, and the Watonwan County Medical Society, and formerly mayor of St. James, died at the hospital on February 4, aged 56 years.

Dr. Paul Pomeroy Allen of Chambersburg, Pa., a graduate of the Medico-Chirurgical College of Philadelphia in 1909, and a member of the Medical Society of the State of Pennsylvania and the Franklin County Medical Society, died at his home from pneumonia, on February 10, aged 29 years.

Dr. Richard Flavel Woods of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania, Philadelphia, in 1895, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the Philadelphia Academy of Surgery, and the Obstetrical Society of Philadelphia, died on February 10, aged 42 years.

Dr. Henry Cecil Haven of Stockbridge, Mass., a graduate of the Harvard University Medical
ary 19, aged 60 years.
School, Boston, in 1879, died at his home on Febru-

Dr. James Joseph Scannell of Boston, Mass., a graduate of Tufts College Medical School, Boston, in 1905, a member of the Massachusetts Medical Society and the Suffolk District Medical Society, and director of the bacteriological laboratory of the Boston Department of Health, died at his home from pneumonia following an operation for gastric ulcer, at the Carney Hospital, Boston, on February 19, aged 39 years.

Dr. Loyal B. Griffin of Greenfield, Ind., a graduate of the Medical College of Indiana, Indianapolis, in 1890, died suddenly at his home on February 17, aged 56 years.

Dr. Omar Alpha Flint of Dracut, Mass., a graduate of the University of Vermont College of Medicine, Burlington, in 1885, a member of the Massachusetts Medical Society and the Middlesex North District Medical Society, and formerly on the staff of the State Infirmary at Tewksbury, died at his home, after a lingering illness, on February 16, aged 71 years.

Dr. Marshall Jacob Brown of Kingston, Ont., a graduate of Queen's University Medical Faculty, Kingston, in 1856, died at his home on February 14, aged 83 years.

PRIORITY IN THE USE OF CITRATED BLOOD FOR INFUSION.

To the Editor of the Medical Record:

Sir:—In the article on "Transfusion of Blood by the Gravitation Method," published in No. 9 of The Medical Record, Dr. Rueck states that he infused 250 c.c. of citrated blood in May, 1914, and says: "Since Dr. Lewisohn acknowledges that he has experimented with sodium citrate solutions only for the last few months, since my experiments are of a much older date, and since I explained my method to the staff of St. Francis Hospital and several medical friends last summer I claim to be the originator of this method of blood transfusion."

As I stated in my article (Medical Record, January, 23, 1915) the priority for using citrated blood in the human blood-transfusion belongs to Hustin of Brussels, who reported his method nearly one year ago. This fact settles any discussion on priority between Dr. Rueck and myself.

TROPICAL IRRITABILITY.

To the Editor of the Medical Record:

Sir:—In observing a number of symptoms which are peculiar to certain individuals living in the tropics we may be able to frame up a pathological picture that may be called "Tropical Irritability." Describing this condition we may say that we are dealing with a case of nervous hypertension. It is seen in adults, both male and female, of any race and social standing, but it is noticed especially in the lower classes.

The patient is generally pale, thin, and with a worried expression. His talking is exaggerated and accompanied by rhythmical movements of hands and eyes, placing himself in a somewhat dramatic posture. Outside of these peculiar points the patient is normal in all his functions and faculties.

Discussing the etiology of this condition we may blame many causes for it, as inheritance, hard life, climate; but I am inclined to believe that the most important factors are tobacco and coffee used in excess, as by withdrawing these two substances and giving a general tonic, the patient gets well in a short time.

A. Montalvo Guenard, M.D.

Mayaguez, P. R.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PUERPERAL ECLAMPSIA DISCUSSION—THE WAR; SIR J. FRENCH'S DISPATCH ON TWO MONTHS' HOSTILITIES —NATIONAL SCIENCE RESEARCHES—TYPHOID AND PARATYPHOID FEVERS—INOCULATION—OBITUARY.

LONDON, Feb. 19, 1915.

THE Midland Medical Society had a special discussion at Birmingham on the 27th ult. on puerperal eclampsia. This was opened by Dr. C. E. Purslow, who is obstetric officer to the Queens Hospital, consulting surgeon to the Maternity Charity, and lecturer on midwifery and diseases of women at the University of Birmingham. For the purpose of discussion, he spoke of the subject under these three sections: 1, Prophylactic treatment; 2, treatment of the fits and of the toxemia; 3, obstetric treatment.

1. As regards the first he had no doubt that when threatened the disease may in many cases be warned off, success depending on early recognition of the symptoms of the pre-eclamptic state. These are numerous, but the most constant and important are albuminuria, persistent headache, and edema. Other symptoms may be disturbances of vision and hearing, and vomiting. Epigastric pain is not common as a prodromal symptom, but when present Dr. Purslow looked upon it as most unfavorable from the prognostic point of view. Pronounced albuminuria in the later months of pregnancy (eclampsia in the earlier period being rare) was dangerous for both mother and child. The danger is increased by its being too often unrecognized and so untreated until a convulsion suddenly occurs. He advised a rule to examine every pregnant woman at intervals, shorter as the time approaches. Such rule would diminish the death rate of eclampsia. A haze may be due to mucous discharge, so when present it should be confirmed by a catheter specimen. When albumin is present he thought microscopic examination and estimation of urea advisable. When albumin is in considerable amount the patient should at once be sent to bed on strict diet. A good plan was no solids, nothing whatever but water for the first forty-eight hours. Afterward milk, well diluted until there is distinct improvement in the function of the kidneys. Free purgation should be added, jalap or sodium sulphate every two hours until full action; then the bowel washed out with normal saline fluid. If in spite of this no improvement in the renal secretion occurs or if the prodromes of eclampsia come on, the difficult question of the induction of premature labor arises. On the whole, Dr. Purslow is not in favor of it, as he has seen very satisfactory cases of the foregoing treatment followed by spontaneous delivery without eclampsia, which had seemed on the very verge of occurrence.

2. During the fit, and the practitioner is usually sent for then, often not before, as neither the patient nor her friends have suspected anything wrong in her state. Bed at once in a darkened room, preservation from any irritation as far as possible, an efficient nurse to be instructed that if another fit occurs watch patient to see that no harm befalls her, as suffocation by bedclothes, falling out of bed, biting the tongue (a wedge). Putting one side of the bed against the wall make control easier. In the coma which follows the head should be brought to the bed's edge and turned over so as to let the saliva escape and not get access to the trachea. For the poor admission to a maternity hospital is most desirable in these cases. If the patient can swallow, water, but no food may be allowed, not even milk. A quick-acting aperient—ol. croton, ♏ ij, is one of the best, put on the tongue; a copious enema, soap and water, may be added, and when this has acted one of 2 ounce magnesia sulphide in four of water. Washing out the stomach is also good. Most writers agree in addition on the value of saline injections (subcutaneous or intravenous), and Dr. Purslow says Horrocks' small apparatus should be carried in every midwifery bag. Of other treatment Dr. Purslow spoke of (*a*) chloroform, to be used whenever any operative interference is contemplated, even so slight as puncture of the membranes, but he opposed attempting to control convulsions by its continuous administration. (*b*) Morphine—he has tried its hyperdermic use as advocated of late years but is not convinced of its advantages and says as much of venesection. Thyroid, nitroglycerin, veratrum viride were mentioned with their advocates but do not seem to have given him much satisfaction, while he pronounces pilocarpine dangerous. Oxygen inhalations seemed desirable if cyanosis were marked symptoms. Cold baths might be useful if hyperpyrexia was present. Decapsulation of kidneys and lumbar puncture have been practised to a limited extent, but without striking success.

3. Obstetrical authorities are divided into two hostile camps. The Rotunda school believes the toxin is elaborated from the mother's food by fault in her metabolism. The German school blames the fetus, the former advise little interference, the others advocate the most active measures. Dr. Purslow himself, if labor has started and can be terminated quickly, under chloroform, by forceps would not hesitate, but the difficulty is in severe cases, fit succeeding fit, with no lucid interval, and cervix closed or not taken up. He has tried both plans. Three years ago in Latham and English's system he thought results were slightly better with no interference. Now with further experience he seems to incline to the other side. But he is emphatic that if interference be decided on it should be by rapid methods under anesthesia such as dilatation by Bossi's dilator or vaginal or abdominal cæsarean section. But a good trial of milder methods, he thinks, would lead to better results than have been obtained by heroic operative procedures.

In the course of an elaborate dispatch our commander in chief, Sir John French, F. M., gives an account of the last two months' fighting at the front. In this he says that from the commencement of hostilities the work of the Royal Army Medical Corps has been carried out with untiring zeal, skill, and devotion. Whether at the front under conditions when casualties were heavy and accommodation had to be improvised, or on the line of communications, where an average of 11,000 patients have been daily under treatment, the organization of the medical service has always been equal to the demands made upon it. The careful system of sanitation introduced into the army has, with other measures, kept the troops free from any epidemic. Since the commencement of the war only some 500 cases of enteric have occurred. The organization for the first time of motor ambulance convoys is due to the initiative and organizing powers of Surgeon-General J. T. O'Donnell, D. S. O., ably assisted by Major P. Evans, R. A. M. C. Two

of these convoys, composed entirely of Red Cross Society personnel, have done excellent work under the superintendence of regular medical officers. Twelve hospital trains ply between the front and the various bases. The field marshal says he visited several of these trains when halted in stations, and found them conducted with great comfort and efficiency. During the more recent phase of the campaign the creation of Rest Depots at the front has materially reduced the waste of men on the line of communications. Since October the medical arrangements have been in the hands of Surgeon-General Sir A. T. Sloggett, C. M. G., K. H. S., under whom Surgeon-General T. P. Woodhouse and Surgeon-General T. J. O'Donnell have been responsible for the organization on the line of communications and at the front respectively.

Drs. Drezer, Walker, and Gibson, working for the National Medical Research Committee, have found it extremely important to distinguish between cases of typhoid and paratyphoid fever. If this is not done the statistics as to the protection of inoculation will become unreliable. They found no case of typhoid among the inoculated. But of six of paratyphoid three were in such subjects, so if they had been returned as "enteric" the statistics would have shown less value in the protective. So far as these cases go paratyphoid has occurred with equal frequency in inoculated or non-inoculated persons. This agrees with the findings of Kabeshima and others who found antityphoid inoculation afforded no appreciable protection against paratyphoid infection. His recent work in the Japanese navy shows the great protective value and innocuous character of paratyphoid inoculation. He used a mixed vaccine containing equal numbers of typhoid and paratyphoid (A and B) bacilli, inoculating about 12,000 men. He says when a vaccine is made thus of the three organisms in equal proportion, and given in dose equal to a dose of antityphoid alone, the effect is not significantly greater and it seems certainly better than immunizing against each organism successively. The conclusions offered by these three observers are that it is of the utmost importance that our troops be protected against paratyphoid infection as well as *B. typhosus*. This can be done by using a mixed vaccine. Men who have been inoculated against the *B. typhosus* should take the further protection against the paratyphoid infection. The epidemics of typhoid reported from time to time after inoculation are probably epidemics of paratyphoid. Unless all cases of enteric are properly differentiated into typhoid and paratyphoid the value of our statistics in the present war will be most seriously vitiated.

The War Office after consultation with the local governing board have decided that a special record shall be kept by military sanitary offices of every case of enteric fever among our soldiers. Material will thus be provided for further inquiry when multiple cases occur, will afford comparison with the experience of various military units, and enable a summary to be prepared of the experience of the army as a whole and in different parts of it. The scheme involves the co-operation of the medical officers of health in the sanitary districts where troops are stationed with the military medical officers in tracing the sources of infection and removing any conditions favoring the spread of the disease.

The Home Office has drawn the attention of local authorities to the importance of enforcing strictly the provisions of the Factory Act as to home work in connection with clothing for the army. Great care should be taken to see that the work is not done in premises where there is infectious disease. The local authorities have full powers, and the Secretary of State hopes where they have not already they will at once arrange for close and special attention being paid by their officers to premises where army clothing is made.

The medical committee of the Science Guide has passed a resolution of extreme dissatisfaction at the publication of an advertisement dissuading soldiers from inoculation against typhoid—an invaluable procedure for the preservation of the health of the troops in the field. The advertisement is injurious alike to humanity and the conduct of the war.

The usual meeting of members of the British Medical Association, which had been fixed for Cambridge, will not take place this year on account of the war. The statutory meeting and the meeting of representatives will be held as usual.

Dr. Henry Montague Duncan, probably the senior medical man in London, died on Wednesday at the age of 92. He was a University College student, in general practice in Buckingham Palace Road from 1850 to 1880. He retired in 1900.

6. A Water-Tight Ureteral Catheter Tip. F. H. Lahey.

1. Locating Needles in Tissues.—G. H. Monks has demonstrated the feasibility of locating needles in tissues with the aid of magnetism. The procedure is as follows:—(1) The buried needle is magnetized by passing a magnet over the locality where this needle is supposed to be. The best results are obtained when the long axis of the magnet is in the same line as the axis of the needle. (2) The examining needle (suspended in the middle from a fine silk thread) is then slowly passed over the same locality. In the event that it passes over the buried needle,—provided that needle is not too far away from the surface—one end or the other of the examining needle will be attracted and will dip in the direction of the buried needle somewhat in the same manner as the "divining rod" is said to do, when that rod is brought to a place on the ground under which water can be found. As the buried needle, after it has been magnetized, has two poles (N and S), and as the examining needle has also two poles (N and S), it follows that (according to the physical law, that "like magnetic poles repel one another, unlike poles attract one another") the N pole of the examining needle is attracted to the S pole of the buried needle, and the S pole of the examining needle is attracted to the N pole of the buried one.

4. Diverticulum of the Bladder.—H. Cabot notes that some confusion has arisen through failure to separate the different types of pouches or diverticula which are found in the urinary bladder. Thus the small hernial protrusions between the muscular fibres which occur in the subjects of chronic urethral obstruction bear no relation to true diverticula. They are simply the result of weakness of the bladder wall when put under strain; are directly due to the obstruction and lose

their importance when that obstruction is removed. The pouch connecting with the vertex of the bladder, due to failure of closure of the urachus, should also be distinguished from the genuine type of diverticula since it is in and of itself a perfectly definite failure of development, occupies a constant position and is comparatively unimportant in the surgery of the bladder. The word "diverticulum" should be confined to those cases of pouches, always of congenital origin, occurring most frequently in certain positions, but occasionally seen in almost any portion of the bladder and not due to defective development or lack of closure of any recognized structure. The author does not agree with the view expressed by Chute in a recent paper, that they originate in the little pouches normally seen just above the ureteric orifice, and that they become important only when this pouch is exaggerated as the result of obstructive pressure. Diverticula are frequently found in individuals in whom obstruction is totally absent, in whom in fact the symptoms of obstruction are due, not to any obstruction, but to the diverticulum. When found in individuals with urinary obstruction, they are an accidental finding and of no etiological significance. That they are due to some embryonic defect is clear, but there is no adequate explanation of their formation beyond the fact that they are associated with peculiarities of the closure of the cloaca, perhaps with a tendency to budding from this structure.

10. Catharsis After Operation for Appendicitis. L. B. Meyer.

1. Epilepsy.—L. Pierce Clark contends that neither the present accepted pathological anatomy of marginocortical gliosis nor its postulated pathogenesis, a still earlier chemicotoxic state, is really sufficiently constant in variation and extent to account for essential epilepsy; that one must seek for an alteration in some more fundamental process of life, absence of which shall be sufficiently dynamic to cause the mechanism of the epileptic fit in all cases of the genuine disease; that a definite defect in the emotional or affective side of the mind in epileptics is constant though variable; that the fit is a striving for expression of the libidinous energies in the unconscious; that the fit is therefore a libidinous outlet of the primal sexual energies and should be considered as essentially a pathological functioning of the unconscious; that this state is due to a condition of mental infantilism caused by or coincident with a libidinous fixation in the earlier stages of psychosexual development of the epileptic; that the most constant fixation defect is one of more or less rigid attachment to the parent of the same sex as the epileptic himself; that other libidinous objects of attachment or fixation may be shown at the same time to be narcissistic and homosexual; and that the prognosis and treatment of the malady should be based upon the strength of the primary, secondary, and tertiary libidinous energies, and upon how far they may be made to assume a proper normal direction of development in subrimation.

10. Catharsis after Appendicitis Operation.—L. B. Meyer describes his routine management of the bowels after laparotomy for peritonitis or for uncomplicated appendicitis as follows: (1) Not to bother the patient for forty-eight hours unless he is uncomfortable or there are evidences of progressing distention. (2) At the end of forty-eight hours, or before if necessary, a low soapsuds enema is given. If effectual, a similar enema is given once in twenty-four or forty-eight hours, according to necessity. If ineffectual, a high oxgall enema is given, to be followed every three or four hours by high enemas containing various medicaments, supposedly helpful in such cases, as peppermint, turpentine, asafetida, milk and molasses, etc. The application of hot turpentine stupes during this time is very helpful. If these means prove ineffectual (and this happens very rarely), the question of secondary operation with possibly enterostomy comes up. The author has used atropine and eserine with only indifferent success.

6. Typhoid Prophylaxis.—E. H. Trowbridge, B. A. Finkle, and E. M. Barnard state that typhoid fever may be contracted by individuals who have received the prophylactic and who subsequently show a positive Widal. The course of the disease is not appreciably shortened in vaccinated individuals. The mortality is markedly reduced among protected persons. Protected persons having typhoid fever fail to give many of the classical symptoms of the disease. The development of paratyphoid is not prevented by the use of the typhoid prophylactic. The degree of immunity conferred by the prophylactic in some cases fails to prevent the development of typhoid when the individual has been subject to repeated exposure. The Widal reaction as a criterion of the presence of immunity is of uncertain value. Typhoid vaccination applied as a routine measure in all of hospitals and institutions is the only method by which to eradicate this ever present, serious, and often fatal disease.

8. Critic Salts in Congestive Dysmenorrhea.—B. L. Spitzig has suggested that increased viscosity of the blood takes part in the production of dysmenorrhea. The causative factor is faulty hygiene, defective elimination, nitrogenous overindulgence, sedentary occupation, and tight lacing. At the time of uterine congestion, the blood in this organ is more viscid, and with the accompanying stasis there is greater infiltration of serum into the neighboring tissues. This induces a change in the chemical equilibrium of the endometrial cells by causing the cellular colloids to absorb more serum and transforming this gelatinous material into a viscid mass. The effects are greater distention of the spongy layer and increased vascular stasis and mucus production, with the consequent shedding of fibrinous and thrombotic membranes. With this morbid state the ovum cannot readily engraft itself, and sterility is a frequent sequel. Reducing the viscid blood inhibits the formation of clots and membranes; stasis is diminished

and excessive edema of the endometrium retarded. Bleeding through the glands is increased, and diapedesis through stroma and epithelium lessened. In regard to treatment, nitrogenous food raises the viscosity of the blood, and accordingly is restricted before the menses. Catharsis depletes the portal circulation, and at times a hot compress is applied for the purpose of relaxation. The important procedure is the reduction of viscosity through the use of sodium citrate, 20 grains three times daily, during the week or two preceding the expected period. The mode of action is peculiar to the citrates. Diuresis does not explain the results. It seems probable that the alkaline citrate neutralizes carbonic acid and other waste products and increases oxidation, thus proving to be the most efficient method for preventing cellular edema and diminishing viscosity.

The Lancet.

1. Gunshot Wounds of the Head. Sir Victor Horsley.
2. The Pernasal Operation for Frontal Sinus Suppuration by the Anterior Route. P. Watson-Williams.
3. Lipemia Retinalis. R. F. Moore.
4. The Operative Treatment of Bullet Wounds Involving the Vertebral Canal and Associated with Complete Paralysis. L. J. J. Muskens.
5. A Case of Acute Tetanus with Recovery. A. G. Whitehorne-Cole and W. M. S. Robinson.

1. Gunshot Wounds of the Head.—Sir Victor Horsley refers to the results of experiments made by him twenty years ago in which it was shown that the so-called explosive effect of high-velocity bullets is directly proportional to the sectional area of the bullet, to its velocity, and to the amount of water present in the substance through which the bullet passes. The most practically important points with reference to gunshot wounds of the head are: where in the course of the bullet is most mischief done and by what force is this damage effected. The maximal disturbance is produced as soon as the bullet at its highest velocity is surrounded by the largest mass of wet tissue. The forces producing the injury relate to the two movements of the bullet—its progression forward and its spin around a central axis given to it by the rifling. The disruption of the tissues must be attributed in the main to the rotating forces of a bullet, deep penetration of the brain by a fragment of bone is in the first place the simple consequence of the high velocity of the bullet being communicated to such bodies much lighter than itself, and therefore capable of proceeding as far as and even farther than the shot. In view of the fact that any such fragment may be infected, it follows that at the first operation every reasonable search must be made for fragments as they certainly may later cause the death of the patient. Fatal concussion may occur without penetration of the skull. The most paralyzing effect on the centers of organic life are produced most easily by force applied in the frontobulbar axis and the effect of shock applied to the frontal region is transmitted largely by the cerebrospinal fluid to the interior of the ventricles and even to the fourth ventricle. Sepsis in the vast majority of cases is due to the incomplete disinfection of the original wound and to the expectant treatment of head cases. As regards functional disturbance of the brain there is no evidence of compensation by education or substitution of function in other parts of the brain for function lost by reason of permanent destruction of given areas.

3. Lipemia Retinalis.—R. F. Moore states that lipemia retinalis occurs in young diabetics who are usually bordering on coma, and it consequently implies an immediately grave prognosis, but recovery from the condition may occur. It implies a high degree of lipemia, and probably in no condition other than diabetes does lipemia attain a sufficiently high degree to give rise to the appearances of lipemia retinalis. Vision may remain unaffected in spite of a very high degree of lipemia retinalis. The conspicuous changes in color and appearance of the retinal vessels are probably entirely dependent upon the opacity of the plasma, and do not indicate a change in the hemoglobin. Lipemia retinalis supplies so striking and characteristic an ophthalmoscopic picture that it cannot be overlooked or mistaken for any other condition.

2. The Wassermann Reaction in Ophthalmic Practice.—W. H. Manson, T. J. Mackie, and H. E. Smith conclude from their investigations that excluding such conditions as ocular injuries, conjunctivitis, cataract, and the ordinary errors of refraction, if all other ocular affections without selection are analysed on the basis of the Wassermann test, practically 50 per cent. of these collectively are associated with a positive reaction. Since many of such lesions occur in the tertiary and latent stages of syphilis in which only a certain proportion yield a positive result, it is a justifiable presumption that this is probably an under-estimate, and that syphilis plays an even more prominent part in the production of ocular disease than our figures show.

3. Dupuytren's Contraction.—K. Black describes the treatment of this condition as follows: In the earlier stages of the disease, when there is the slightest tendency to contraction, the patient should wear, at night only, a well-padded splint on the affected finger, for the purpose of hyper-extending it. Care must be taken to avoid giving pain, for pain would indicate that the extension was excessive, and more harm than good would be done. In combination with "extension," manipulations, massage, hot water, and Bier's treatment are useful. Fibrolysin injections have been tried, but the results cannot, on the whole, be regarded as encouraging. Ionic medication has also been tried. Leopold-Levi, who believes that Dupuytren's contraction is a symptom of thyroid deficiency, tried internal treatment with thyroid extract in 7 cases, with favorable results in 5. The daily dose consisted of 10 centigrams of thyroid powder, and in one case as many as 163 doses were given. When non-operative treatment fails, and in advanced cases of the disease, an operation is necessary. Apart from amputation (which, of course, must be reserved for exceptional cases of a very troublesome kind) there are two operations, known as the open and the subcutaneous respectively. In the open operation skin flaps are dissected from the palmar fascia; the palmar fascia is then excised and the wound is closed. The greatest care must be taken to keep the parts asceptic, for if the wound suppurates the operation will fail and the contraction will become excessive. The operation requires much patience; the dissecting back of the skin flaps from the adherent palmar fascia is troublesome, and the excision of the fascia from the sheaths of the flexor tendons must be done bit by bit. When this excision has been completed the digits, in favorable cases, will be found to be free and capable of being almost completely straightened. At this stage same surgeons rub fibrolysin into the open wound. The skin is then closed, and a well-padded splint is attached to keep the

digits as straight as possible. The splint must be worn for some weeks uninterruptedly and afterwards at night only, until the digits are straight and all tendency to contraction has been overcome. The subcutaneous operation gives excellent results if carefully carried out after the manner described by Adams. A very fine tenotomy knife is inserted between the skin and the tense bands of the palmar fascia, all of which, through as many punctures as may be necessary, are carefully divided. Generally, from six to ten punctures suffice, but in extensive cases as many as twenty punctures may have to be made. A properly devised finger splint is then applied and worn continuously until the digits are straight; afterwards the splint is worn at night only for several months. In the event of a relapse, which is uncommon, the operation can be repeated.

Berliner klinische Wochenschrift.

January 25, 1915.

Vita Sexualis and Warfare.—Touton concludes his long serial article on this subject. He enumerates the provisions of the ordinance of 1907, which is intended for the welfare of the troops in both peace and war, and also mentions the efforts of private societies in this direction. It is anticipated that in time of war, while troops at the front are protected from an invasion of prostitutes, all others not engaged in actual fighting will be exposed to this danger. The women must therefore be intercepted and segregated or rendered harmless before disease can be spread. If when a command reaches a city or town the troops begin to show infection in considerable numbers it will be evident that a number of diseased girls are plying their calling. The military man in charge of the command now places further responsibility on the local civil authority as far as it has to do with the prostitutes. The latter are examined, sequestrated, and treated. In the general round up and policing the troops may assist. Prostitutes who have no disease must have the signature of the troop commander on their cards. Without such a card none can deal with a soldier. Upon the same document the days for examination are specified. Any prostitute irrespective of her physical condition, who is found among a bivouac of soldiers is punished as a criminal, as is also one who knowing herself to be infected, has relations with a soldier. Brothels existing in any town where troops sojourn receive added supervision at the hands of the army authorities. In case of marked cumulation of infection more drastic measures are required for both the women and the soldiers. The foregoing measures are apparently not official but represent the advice of experts. To what extent they are actually carried out is doubtless not yet known. They have aroused some opposition, because they place no responsibility on the soldier. Upon high patriotic grounds the soldier is adjured by Blashko to practise a relative continence, and in the same spirit to refuse to conceal infection. In other words he should be warned of the great risk of infection to himself and others. The same author mentions the fact that the prostitute cannot exist without the exercise of her calling, and that she could be helped by the State; also that no measures should be pressed which tend to drive loose girls who work as servants into open prostitution. It is claimed by some that new syphilis in troops can be treated during a campaign by intensive methods (injections of mercury and salvarsan). Ulcus molle may or may not cripple a soldier for the time being. Acute gonorrhea is the worst of all three diseases in marching troops, owing to the great risk of severe local and general metastases. These cases may be interned briefly for an abortive cure of an intensive character. These compromise views are propagated by Neisser, who is termed by Touton an extreme optimist. He, himself would not think of allowing any soldier recently infected with any one of the venereal diseases to march. The danger of transmitting syphilis by means of drinking cups, etc., would be great. He would fight disease through special field and reserve hospitals, like any other contagious or infectious malady. Intensive and abortive measures he sanctions. These institutions could also be utilized for prisoners or others who are found to suffer from leprosy, frambesia, glanders, and even favus and severest ordinary dermatosis. Universal disinfection, sequestration, etc., would naturally prevail in all such conditions.

Münchener medizinische Wochenschrift.

January 26, 1915.

Rumination as a Result of Accident. — Wollenburg concludes a long serial article on this subject as follows: The history is that of a man apparently healthy who had experienced nausea from the accidental drinking of certain nonpotable water. He suffered much from rumination for the next two years or so, but sought no medical aid. During this period he followed his calling and did important work. He did not deny himself his alcohol indulgence. Three years after the accident he sought medical advice because of failing capacity for work. At the examination diminished vision and arteriosclerosis were found, while chronic indulgence in alcohol had produced a chronic gastritis. It was therefore no easy matter to connect his general condition with the rumination. The latter was thought to be of the false variety, *i.e.* voluntary regurgitation. Observation had shown that patient appeared to nurse his malady rather than to fight it. Again in true rumination the victims do not complain, nor look on themselves as invalids. It further appeared that the patient was well nourished, and neurasthenia and hysteria could be excluded. The medical opinion, while not attacking the good faith of the man, ascribed his falling off in efficiency to causes other than rumination.

Warfare against Sexual Disease in the Field.—Bruck has been stationed for several months at a captured French city of 80,000 inhabitants, in charge of the venereal section of the German military hospital at that point. The German troops quartered here showed numerous cases of venereal infection. There were no brothels, the diseases being transmitted by free prostitutes who were to be found in the saloons and other like resorts. The soldiers naturally had no means of identification of the unregistered women. A German officer was detailed to prevent these infections, and worked in concert with a French policeman, under the direction of a staff physician. The infected men were led to point out certain diseased women who were detained and interned for treatment. This step had a terrorizing effect on the prostitutes as a class; and the number of infections became reduced to the so-called normal figure. This was, of course, purely a war measure which is not resorted to in times of peace. Of numerous women examined, only a portion had clinical gonorrhea as shown by reddened meatus and os, with discharge. But in all others the microscope showed that while the urethral secretion was relatively sterile, that from the cervix contained gonococci in every case. Two soldiers had chancroids, but the two women examined proved to be free from these lesions. However, in both cases Ducrey's bacillus was found in smears from the urethra and vulva, while the secretions of vagina and uterus were free from it. These finds go to show that this organism may exist as a saprophyte in the external female genitals.

Pneumococcic Peritonitis of Extragenital Origin in a Puerpera.—Wetzel reports a case of this very rare association. In a few cases found in literature the infection seems to have been genital. or doubtful. To fulfill the conditions of the author's case a puerperal local infection should be excluded; a primary pneumonia or pneumococcus sepsis should attack the uterus by metastasis or as a direct extension of a peritonitis into the adnexa. The author's patient had double pneumonia, double pleurisy—both primary—and secondary peritonitis due perhaps to migration of the pneumococcus through the lymph spaces of the diaphragm. To explain the endometritis a blood infection was invoked. The infant died of pneumococcus sepsis contracted from this endometritis. The author excludes all possibility of a migration of germs from the peritoneal cavity to the uterus, either through the walls of the latter or by way of the tubes.

Results of Radium Treatment of Cancer.—v. Eiselsberg, reporting on the use of radiotherapy in his clinic, states that while the effect of radium and the *x*-ray upon superficial carcinomas has long been proven, their efficacy in deep-seated tumors still remains a much mooted question, and whoever has had any experience that might help to clear up the situation, should certainly publish it for the benefit of others. He mentions Funke's case of carcinoma of the gingiva reported before the German Congress of Surgeons in 1908, in which the radium rays so influenced the always recurring tumor that for years local operations could be successfully performed. He reports a series of personal cases in which radium was used as a curative agent as well as for prophylactic purposes, although as to the latter, he believes it will always be difficult to form a correct estimate, particularly as they always aimed to do as radical an operation as possible. The amount of radium at their disposal was 225 mg. He reports four cases of carcinoma of the tongue in which he believes prophylactic radium treatment did more harm than good.

Of the cases in which radium was used as a curative agent, 11 were benefited. They are very briefly as follows:

1. Basal-celled carcinoma of nose, tumor disappeared; patient well 5 months.
2. Frontal epithelioma (basal-celled carcinoma) entire disappearance. (Period of observation not stated.)
3. Epithelioma of face, recurrent (basal-celled carcinoma) disappearance; (duration not stated).
4. Basal-celled carcinoma of skin of face (nostril) and tumor of superior maxilla; radium used on the former; disappearance; tumor of the maxilla became disintegrated and sloughed away spontaneously without direct treatment; patient free from recurrence 9 months.
5. Epithelioma of nose (basal-celled carcinoma) disappeared; time not stated.
6. Rapidly growing epithelioma of face (basal-celled) very much benefited; ulcer is rapidly healing.
7. Frontal epithelioma of 3 years' duration; well and free from recurrence 2½ months.
8. Epithelioma of dorsal surface of hand; good local result, 2/3 of area healed; poor general condition, arteriosclerosis; death 2 months after last treatment.
9. Inoperable carcinoma of tongue involving submaxillary glands; complete disappearance of tumor of tongue; an immovable gland became movable and could be extirpated. Histological examination showed it to be carcinomatous. Later history not known.
10. Large round-celled sarcoma of axilla; incomplete operation; disappearance of the glands that could not be removed; well 9 months. (Prior to complete disappearance of tumor, patient had erysipelas due to a burn).
11. Inoperable carcinoma of an aberrant thyroid gland; pronounced dyspnea; disappearance of latter; obstinate ulcer resulting from a burn was later excised and a plastic operation done; greatly improved when seen nearly 2 years later. (Clinical diagnosis only.)

v. Eiselsberg then gives a list of 16 cases of carcinoma treated by radium with temporary improvement. In 7 cases the curative application of radium was unsuccessful; in 5 cases the treatment was injurious, causing sanious discharge and disintegration. In 6 cases cachexia was hastened by the treatment.

In 5 cases the radium treatment caused hemorrhage. In one case, a sarcoma of the forearm in which radium was used as a prophylactic after operation, a local recurrence took place which promptly disappeared under radium; further recurrences in the neighboring tissues again disappeared under radium; local and metastatic recurrence (head); excision and prophylactic radium treatment. Patient in exceptionally good condition 2 months later. Subsequently treated with nostrum; reported in good condition a year later. Inasmuch as in the majority of these cases radium at first caused a decrease in the size of the tumor, v. Eiselsberg believes that possibly with greater knowledge as to proper dosage, better permanent results will be obtained. Nevertheless, he states, it is a noteworthy fact that in all cases in which the tumor disappeared under radium, autopsy revealed metastases in internal organs, showing that radium is a local remedy only. v. Eiselsberg states that basal-celled carcinomas of the skin are greatly benefited by radium. In 7 of 8 cases the result was good; in the eighth case the patient died of old age before the tumor had completely disappeared. He found the action of radium extremely intensive, but not elective upon the carcinoma. The carcinomatous tissue was destroyed in nearly all cases, but also other tissues, such as vessels. If radium, when slowly destroying a vessel, causes erosion, the hemorrhage may kill the patient before help can be obtained. Radium destroys brain substance and produces meningitis.

In order to remain absolutely objective when judging a successful case, it is necessary to bear in mind that there are cases which, in spite of incomplete operation or no interference at all, remain well for a long time, others that remain free from recurrence for a long time, despite microscopical findings pointing to extreme malignancy. These cases are rare, but must be considered when testing a method as to its value. But despite all these limitations, v. Eiselsberg believes that radium therapy should be adhered to in the treatment of inoperable tumors. It should be the aim of the profession to improve the technique and to learn how burns and subsequent necrosis may be avoided.

With regard to the Roentgen ray in the treatment of inoperable malignant tumors v. Eiselsberg believes on the basis of the cases reported (10 of his own and 6 by other men frequently examined by him), that while none of the cases has been observed sufficiently long to merit being classed as a permanent cure, the results are nevertheless encouraging. He believes in strong dosage, as introduced by the Freiburg school; too small doses he considers not only inefficient, but injurious. He states that inasmuch as the Roentgen rays make it possible to cover evenly a larger area than can be done with radium, the former would seem more suitable for prophylactic purposes. Radium often gives rise to irritation, thus favoring a recurrence; certainly, the treatment of the more deeply-seated tumors should be reserved for the *x*-rays.

v. Eiselsberg's conclusions are: (1) That the treatment with radium or the *x*-ray, but especially the former, is purely local, being confined to the area rayed; contrary to the Roentgen rays, radium is not to be used in deep-seated tumors. At times it may be advisable, after removing as much as possible of the tumor by operation, to give combined *x*-ray and radium treatment. (2) Much remains to be learned yet as to the proper application of these remedies, especially radium. (3) In view of the success so far obtained with the *x*-ray and radium treatment, operation still remains the procedure of choice in all operable carcinomas. It is wrong to have the patient choose between operation and either Roentgen or radium rays. (4) The results obtained with radium and the Roentgen rays are as yet of too short duration to justify their classification as permanent cures. On the other hand, the results following Roentgen treatment have been sufficiently striking to offer hope for the future.—*Archiv für klinische Chirurgie*, Bd. 106, H. 1, 1914.

Daily Fluctuations in Body Length.—Takenami and Iwasaki found an average daily variation of 1.68 centimeters in the Japanese. A decrease in body length occurs after exercise such as marching and boxing and after a hot bath. Iwasaki found that the diminution occurs chiefly in the trunk, and is to be attributed to a change in the curvature of the spine, and to a diminution in the amount of water in the intervertebral cartilages.—*Sei-i Kwai Medical Journal.*

Insurance Medicine.

Examination of the Urine in Life Insurance Work.—Because of the variety of tests employed by medical examiners of life insurance companies for the detection of albumin and sugar in urine, Dr. Whitfield Harrall considers it of the greatest importance to discuss the best tests and the ones recommended by experience and practical examiners.

Chronic nephritis and diabetes are among the most common causes of declination in individuals who apply for insurance. The applicant, not infrequently, is first advised of his condition by the examiner, as these diseases produce no symptoms in their incipiency. Careful and accurate examination of the urine is one of the most important duties of the examiner. Because of the numerous tests suggested, the Association of Life Insurance Medical Directors recommended the following four tests as being the simplest and giving the best results.

Clean test tubes and fresh reagents are absolutely essential. Fehling's solution should be prepared by a reliable druggist, should be kept in separate glass-stoppered bottles, and should be renewed every three months. A separate pipette should be kept for each solution. Haine's solution is supposed to keep fresh indefinitely, but it should be freshly prepared at least once a month. Concentrated nitric acid must not be used after it has become discolored. Tests for albumin should not be made or read by artificial light. Tests for sugar, if made by artificial light, should not be read until natural light is available.

Detection of Albumin.—If urine is cloudy filter through filter paper before making any tests for albumin. Never filter through French chalk, Fuller's earth, bismuth subnitrate, magnesium carbonate, or charcoal.

Allow urine to cool before testing for albumin. Do not use albumoscope or horismascope. Apply both heat and nitric acid test to every sample—one checks the other.

Never use that portion of the urine to which the heat test has been applied for the nitric acid contact test.

Heat Test.—If urine is acid, take one-half test tube of the filtered urine, add one-sixth of its volume of saturated salt solution (five ounces to the pint), hold tube by lower portion and boil upper one-third. If a cloud forms it consists of either albumin or earthy phosphates. Add two or three drops of 10 per cent. nitric acid, boil again and add three drops more of the acid; if cloud remains, albumin is present; if the cloud entirely disappears, phosphates are present and no albumin.

If the urine is alkaline or neutral, take one-half test tube of the filtered urine, add one-sixth of its volume of saturated salt solution, then a sufficient number of drops of 10 per cent. nitric acid or 33 per cent. acetic acid, to render faintly acid. This must be done in all cases where the urine is alkaline or neutral, for albumin will not be precipitated from such urine by heat. When this has been done, apply heat as above.

Nitric Acid Contact Test (Heller's Test).—Take a perfectly clean and dry test tube having a caliber of about one inch (conical wine-glass is preferable) and pour into it about one inch of urine; allow concentrated nitric acid to flow slowly from a pipette down the side of the inclined test tube under the urine. Or, place in a test tube of large diameter about one inch, of concentrated nitric acid, then incline the tube and from a pipette allow an equal volume of urine to flow slowly down the side of the tube, carefully overlaying the acid. If albumin is present, by the use of a dark background a zone will be seen just above the point of contact of the urine and the acid, its intensity depending on the amount of alumin present. If no cloud is seen, the test tube should be set aside and re-examined in one-half hour, because the reaction for albumin is sometimes slow.

Detection of Sugar.—One test for sugar is sufficient, except in doubtful cases. It is not necessary to filter the urine. If urine contains more than a slight trace of albumin, remove it by boiling and filtration before testing for sugar. Always test for sugar no matter what the specific gravity.

Fehling's Test.—Take equal parts of the copper and alkaline tartrate solutions in a test tube and add a quantity of water equal to the combined volume of the two reagents used; the total quantity for a test need not exceed 5 c.c. (about 1¼ fluid dr.). Boil the mixture, and if it remains clear it shows that the Fehling's solution is in good condition; then add a few drops of the urine. Warm the mixture but do not boil it, then add a few more drops of the urine; warm again, and continue so until the amount of urine added equals one-half the volume of test solution used. If the specific gravity of the urine to be tested is below 1.020, the urine may be added in equal volume to the test solution. If sugar is present, a yellow or red precipitate of suboxide of copper appears. This occurs quickly if much sugar is present. If the amount of sugar is less than 1 per cent, the reduction will not appear until after several minutes—five to thirty. If a reduction does not appear in thirty minutes, sugar is absent; if the result of the test is still doubtful, the test tube should be set aside from twelve to eighteen hours, and then the sediment examined for any deposit of the suboxide of copper.

Haine's Test.—Take about 4 c.c. (1 dr.) of the solution in a test tube and gently boil; add eight to ten drops of the suspected urine and again gently boil. If sugar is present a copious yellow or yellowish red precipitate of copper suboxide separates; if the amount of sugar present is small the reduction may take from five to thirty minutes. If any doubt exists the test tube should be set aside for from twelve to eighteen hours. A grayish or greenish precipitate of phosphates, which is nearly always thrown by the alkali in Haine's or Fehling's solution, should not be mistaken for a deposit of suboxide of copper, which is always yellow or red. Simple decolorization of either solution by the urine should not be considered a positive reaction, for sometimes a concentrated and strongly acid urine, which is sugar-free, will decolorize the copper; but, a decolorization may mean a beginning reduction of the copper. It is always advisable to let the test stand for twelve to eighteen hours before arriving at a definite conclusion.—*Texas State Journal of Medicine*, November, 1914.

Opinion Is Evidence.—In an action on an accident policy, a question to the insured person's physician whether the insured was incapacitated from attending to his business during certain months by injury was held not erroneous as calling for the conclusion of the witness where the physician had knowledge of the facts.—Hummer v. Midland Casualty Co., Michigan Supreme Court, 148 N. W., 413.

Book Reviews.

A Manual of Dental Anatomy, Human and Comparative. By Charles S. Tomes, LL.D., F.R.S., F.R.C.S. Seventh edition. Edited by H. W. Marett Tims, M.A. (Cantab.), M.D., M.Ch. (Edin.), F.L.S., F.Z.S., University Reader in Zöology, Bedford College, University of London, and Professor of Biology, Royal Veterinary College, London; A. Hopewell-Smith, L.R.C.P., M.R.C.S., L.D.S. (Eng.), Professor of Dental Histology and Comparative Odontology, University of Pennsylvania, U.S.A.; and John Tomes Briseman, of the Royal College of Surgeons of England; formerly surgeon and lecturer on Dental Anatomy and Physiology at the Royal Dental Hospital, London. With 300 illustrations; price, $4.50 net. Philadelphia: P. Blakiston's Son & Co., 1914.

For the first time in the continuation of this work Mr. Tomes' name is not appended to the preface, which is signed jointly by the editors. The subject matter has been so changed about that it is now comprised in two sections. The first may be termed the practical portion, as it is devoted wholly to human dental anatomy as a foundation for the study of dentistry. This section is the joint work of the editors. The second section is simply a treatise on comparative dental anatomy, and is wholly from the pen of Dr. Tims. It is therefore quite proper to speak of the volume as made up of two separate treatises, to each of which is awarded about the same space, so that one is in no sense a mere pendant to the other. Every dentist should acquire the information contained in the first section, while for reference purposes the work may be highly recommended to the general anatomist, histologist, embryologist, stomatologist, surgeon, comparative anatomist, zöologist, etc., as well as to the dentist.

A Text-Book for Midwives. By John S. Fairbairn, M.A., B.M., B.Ch. (Oxon.), F.R.C.P. (Lond.), F.R.C.S. (Eng.). Obstetric Physician, With Charge of Out-Patients and in Charge of Maternity Ward, St. Thomas' Hospital; Lecturer on Midwifery, St. Thomas' Hospital Medical School; Physician and Lecturer to Midwives, General Lying-in Hospital, York Road, S.E.; Examiner to the Central Midwives Board, etc.; Formerly Lecturer to Pupil Midwives, Midwives' Institute. With 3 plates and 104 illustrations; 5 in color; price, $3.75 net. London: Henry Frowde, Hodder & Stoughton; New York: The Oxford Press, 1914.

This is the most advanced book on obstetrics for midwives which has come to our notice. In the preface the author claims that his lengthy experience with this class (in England) justifies the standard exhibited in this volume; and while we are not prepared to contradict him, we do know that the same high standard does not obtain here. Most midwives will find that the instruction contained in this erudite volume is more than they need. The ordinary midwife knows nothing of cocci, staphylococci, streptococci, tetrads, sarcinæ, spirochetes, spirilla, streptothrices, leptothrices, and thiothrices; and is unversed in microscopy, antibodies, and vaccines. The index contains no reference to Walcher's position or to pituitrin.

Pathogenic Microorganisms. A Practical Manual for Students, Physicians, and Health Officers. By William Hallock Park, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Bureau of Laboratories of the Department of Health, New York City; and Anna W. Williams, M.D., Assistant Director of the Bureau of Laboratories; Consulting Pathologist to the New York Infirmary for Women and Children. Fifth edition. Enlarged and thoroughly revised. With 210 engravings and 9 full-page plates. New York and Philadelphia: Lea & Febiger, 1914.

The special feature of this edition, besides the new and revised material, is the rearrangement of the topics. Part I deals with the general characteristics and methods of study of all the microorganisms considered. Part II deals with the pathogenic microorganisms, and their near relatives. Part III presents the subject of applied microbiology. A separate chapter is devoted to complement fixation and its various applications. There is a new chapter on filtrable viruses. In the revised chapter on media the recent methods for the use of aniline dyes have been incorporated. Extensive changes are noted in the chapters on the streptococcus, pneumococcus, diphtheria bacillus, tetanus bacillus, hemoglobinophilic bacilli, bacillus of pertussis, moulds, and amebæ, and in the chapter on rabies. The illustrations are numerous and the nine new colored plates are particularly fine. It can with truth be said of this work that it is strictly up to date, and available both as a textbook and as a work of reference.

Taschenbuch der Therapie. Mit besonderer Berücksichtigung der Therapie an den Berliner, Wiener, u. a. deutschen Kliniken. Herausgegeben von M. T. Schnirer, Redakteur der *Klinisch-therapeutischen Wochenschrift*. Elfte Ausgabe. Price, 2.50 marks. Würzburg: Curt Kabitzsch, 1915.

A new edition of this book appears every year with revisions and additions that keep it in close touch with therapeutic progress. Among the newer features of the present edition may be mentioned the revised section in infant feeding in which are described among other topics the methods of protein-milk and carrot-soup feeding; the section on fractures and dislocations; and the review of therapeutic progress during 1914. The book is said to be particularly adapted to the needs of the young army medical officers engaged in the war in Europe.

The Pocket Formulary for the Treatment of Disease in Children. By Ludwig Freyberger, J. P., M.D., Vienna; M.R.C.P., Lond.; M.R.C.S., Eng.; Barrister at Law; Toxicologist and Pathologist; late Hon. Physician, St. Pancras and Northern Dispensary; Curator of the Museum, Pathologist and Registrar, Great Northern Central Hospital; Clinical Assistant, Hospital for Sick Children, Great Ormond Street. Fourth, revised, and enlarged edition. Adapted to the British Pharmacopœia. With an Appendix on Poisons, their Symptoms and Treatment. Price, $2.00. New York: Rebman Company, 1914.

This handsome leather bound pocket manual contains a succinct description of the drugs adapted for the treatment of diseases of children. The drugs are arranged alphabetically, and under each are considered the properties, use, therapeutics, incompatibles, dose, correction of taste, examples of formulæ, antagonists, and antidotes. One of the important features of this book is the importance attached to the correction of the taste of drugs, a subject of no little importance in the treatment of children. The prescriptions are well selected, and striking for their simplicity and for the ease with which they may be committed to memory.

Case Histories in Obstetrics. Groups of Cases Illustrating the Fundamental Problems which Arise in Obstetrics. By Robert L. DeNormandie, A.B., M.D., Assistant in Obstetrics, Harvard Medical School; Physician to Out-Patients, Boston Lying-In Hospitals; Assistant in Gynecology, Boston Dispensary. Boston: W. M. Leonard, Publishers, 1914.

These case histories comprise those of eighty-four cases that were observed in the author's private and hospital work. They include cases illustrating the diagnosis of pregnancy, miscarriage, normal pregnancy, various abnormal types of pregnancy and of parturition, and the puerperium and its complications. The book embodies all the virtues of the case-history teaching which has been successfully demonstrated in Harvard Medical School. The subject matter of the various topics is presented with a vividness and a concreteness that are possible only with the narration of the actual case, and besides is so systematized as to form a textbook of practical obstetrics.

Pathfinders of Physiology. By J. H. Dempster, A.B., M.D. Editor of the *Detroit Medical Journal;* formerly Lecturer in Physiology, Detroit College of Medicine, etc., etc. Price, $1. Detroit: Detroit Medical Journal Company, 1914.

This is a modest volume of 66 pages which is a reprint of serial contributions by the author to his own journal. He admits that biography writing is his hobby. Under such circumstances serious criticism is hardly indicated. Scores of practitioners are at present engaged in writing up the by paths of medicine with various degrees of fitness for the work, and this movement has been pronounced wholesome in the main. Most of the contents of this book could have been readily adapted from Sir Michael Foster's classical "History of Physiology" (a book which is or ought to be recommended for collateral reading in all medical schools), and Dr. Dempster has sufficiently acknowledged his obligations to Foster's works. At the same time the author's product will doubtless reach many a busy practitioner who would never otherwise have had the opportunity of improving himself as to the lives and activities of the "pathfinders of physiology."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 4, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

A Plan to Celebrate the Fiftieth Anniversary of the Department of Health of the City of New York.—Dr. S. S. GOLDWATER, Commissioner of Health of the City of New York, sent the following letter to the Council of the Academy of Medicine: "For some time health authorities have been very much concerned regarding the definite increase in the mortality of the higher age groups, an increase manifesting itself particularly in certain degenerative diseases like arteriosclerosis, Bright's disease, cirrhosis of the liver and apoplexy, and certain malignant diseases like cancer. Much has been accomplished in recent years in saving infant lives, but it seems difficult to arouse the people, or even the medical profession, to the surpassing importance of instituting hygienic measures for persons in adult life. Dr. Charles F. Bolduan, Director of the Bureau of Public Health Education of the Department, has recently been conferring with a number of prominent health authorities, and suggests that something spectacular is needed in order to initiate the very necessary measures which should be taken to combat this increased mortality. In consultation with Professor Winslow, plans have been discussed for holding an exhibition of adult hygiene in this city in 1916, the fiftieth anniversary of the organization of the Department of Health. This idea has my hearty approval. It seems to me that much would be contributed to the dignity and effectiveness of this exhibit if it were held under the auspices of the Department of Health of the City of New York, the Department of Health of the State of New York, the New York Academy of Medicine, and the American Museum of Natural History. Will you not consent to serve as a representative of the Academy of Medicine in organizing and holding this exhibit?"

The Council recommended that the Academy approve of this scheme and take part in this exhibit.

The Diagnosis and Treatment of Tetanus.—Dr. MATTHIAS NICOLL, JR., presented the results of certain experiments that were made at the Laboratory Research by Dr. William H. Park and himself, the results of which prompted him to ask the cooperation of the physicians in stamping out tetanus, a disease which was omnipresent. This disease was present wherever the excreta of domestic animals came in contact with the soil and city dust, and, therefore, it could not be wholly eradicated from agricultural places. But it was hoped that the disease would be made to disappear, from man at any rate. Tetanus was not a very common disease in times of peace and there were many physicians who had never seen a case. It was the surgeon who saw these cases in the end. It was an odd fact that the wound which was followed by tetanus in New York was not the classical wound described in the literature, that was, the badly crushed extensive wound. The wound was often overlooked because it was so insignificant. In only two of thirteen cases were the wounds severe ones. With regard to the diagnosis, Dr. Nicoll said that in animals inoculated with this organism the symptoms usually first appeared at the point inoculated; but in the human being, for reasons not yet understood, wherever the wound was, the first symptom took place as spasm of the masseter muscle with lock-jaw. Therefore he believed, unscientific as it seemed to be, that the following procedure should be recommended. Every patient with a sudden locking of the jaw, with a hard massetер muscle, in the absence of any positive reason for such symptoms, should be considered as one affected with tetanus and there should be no delay in pronouncing it tetanus, and they should not wait for the diagnosis to be further established before instituting treatment. No harm was done by such a procedure and many lives could be saved. Though the jaw was usually first affected in man, in one of a series of cases there was, however, facial paralysis; while in another there was spasm of the abdominal muscles. He emphasized the fact again that in the absence of other definite cause, if the patient had locked jaws, heightened reflexes, especially the patella reflex without cerebral symptoms, a diagnosis of tetanus was justified. The history of a wound might be definite or even absent. Treatment should be begun at once and no harm could be done if the condition proved not to be tetanus. There was plenty of time to make a differential diagnosis after the treatment had been initiated. It was not necessary to always have the history of a pathological wound. In a number of cases the wound was insignificant, so much so as to be forgotten by the patient. Many wounds would entirely heal long before the development of any symptoms. Every minute lost in the treatment of these cases was a nail driven into the patient's coffin. There was one symptom which was described in the German literature, namely, a contraction of the tissues about the wound. In this country it was usually not noticeable, but it probably occurred. In regard to the treatment of tetanus there was no disease about which it was more truly said that prevention was better than the cure. The best treatment for tetanus was preventive. The use of magnesium sulphate had proven to be rather dangerous; this treatment and the carbolic acid treatment (Baccelli's) together with antitoxin were usually given. The results were frequently disappointing because the treatment was given too late and in too small doses. Until about one year ago Dr. Nicoll said he was about ready to agree that there was little use in the treatment of these cases of tetanus with antitoxin after the symptoms had thoroughly developed. Cases that resulted fatally seemed to be due to a late diagnosis and the existence of symptoms three or four days after the infliction of the wound. Also they seemed to be due to the use of the intramuscular injections rather than to the intraspinal injections. The intraspinal injections had been used throughout the world, but with indifferent results. Neubauer in 1905 reported a series of forty-three cases of tetanus in Europe and in America with a death-rate of 51 per cent. Experimental proof of the value of intraspinal injections was lacking until 1913, and even then it was not convincing. During this year Permin of Copenhagen, experimenting on rabbits, reported the results of his work. Just one year ago Dr. William H. Park and he took up the experimental side of this work, but instead of using rabbits they used guinea-pigs. They first attempted to find out whether the fluid injected into the lower part of the spinal canal would go throughout the spinal canal. By using methylene blue it was found that the fluid was carried not only throughout the spinal canal but even to the ventricles of the brain. Dr. Nicoll presented a chart to show the value of the intraspinal injections. When a call came in for any unusual amount of the antitoxin he immediately tried to get in touch with the doctor. He asked for the cooperation of the doctors in this matter. If any doctor recognized a case as one of tetanus he desired that he would advise with the Department of Health. In suspected cases they recommended intraspinal injections of the antitoxin with the simultaneous administration of intravenous injections. The technique of the operation was exactly like the technique in the administration of the meningococcus serum. The injection of the antitoxin should be given and diluted afterward; this meant that 20,000 units were first injected instead of 100,000 or 150,000, as physicians in New York frequently felt they were called upon to use. Dr. Nicoll said that he recently had seen a statement from France that it was necessary to stand the patient on his head, as it were, in order to get the fluid to travel up the spinal canal. This was not necessary. The fluid would go up the spinal canal without resorting to such a posture; it would go up and bathe the cord. The injection of the serum about the wound he did not believe necessary. Some German thought that the injection should be given in the neck because he could not conceive of the fluid going up in the spinal canal when injected lower down. In a second chart which Dr. Nicoll showed the recovered cases numbered ten, while there were but three fatal cases, making thirteen altogether. In addition to these thirteen cases charted he had recently received reports on three more, all of which recovered. This made sixteen cases altogether, with but three deaths, which he believed was a record in the treatment of tetanus. The Department of Health had sent abroad for use during the present was enough tetanus antitoxin to immunize 1,000,000 men. It was was shipping 10,000,000 units a month to Europe now.

Future Lines of Progress in Child Hygiene Work.—Dr. S. JOSEPHINE BAKER presented this communication, in which she stated that public health work for children had steadily deviated from the preconceived ideas of the relation of health boards to the community, and had become an expression of the social conscience of the people, together with a desire on the part of health authorities to direct and educate, rather than to correct

and punish. It was a vital principle of the new public health creed that was eliminating the dogmatic edict, "This you must not do," and substituting the hopeful message, "This you must do, and we will help you." This ideal had been partially achieved by the Bureau of Child Hygiene of the Department of Health of New York City. Of the 362 sections of the new sanitary code only five related directly to the work of the Bureau of Child Hygiene. Little legislation was needed in carrying out a program of child hygiene work. Its basis was a system of public health education; hence the program for future achievement must emphasis educational and preventive health work. In discussing the relation of the midwife problem to child hygiene, the speaker said that, owing to the department's established standards and the individual and collective supervision of these women, they had maintained a very creditable record in regard to the occurrence of ophthalmia neonatorum in the babies under their care and of puerperal septicemia in the mothers, and in the number of stillbirths or deaths during the first week of life. At the present time midwives were caring for about 37.5 per cent. of the births in the city, a yearly total of about 53,000 confinements. At the present time the lying-in hospital facilities of New York were absolutely inadequate to meet the need of caring for this large number of cases, and even if the need were met there were many who still refused to go to hospitals and who demanded care at home. In attempting to solve the "midwife problem" the medical profession as well as the laity must not only be conversant with the present firmly entrenched position of these women, but must recognize that, on the whole, they were rendering efficient service. They could not and should not be eliminated, but the limitation of their services should be sharply defined and maintained, and their standard of practice raised to a high level of efficiency. The reduction in the infant death rate was probably the most notable contribution that organized child hygiene work had made toward the welfare of the community. Throughout the cities of this country the results of this work had been striking, and progressively efficient. For 1914, New York City had shown a death rate of babies under one year of age of 94.6 per 1,000 births, the lowest infant death rate of the ten largest cities in the United States. The point should be emphasized that all effective work for the reduction of infant mortality must be founded upon the direct idea of the reduction of infant morbidity. Any campaign merely to keep babies alive must necessarily be a failure because such children might easily succumb during the second or third year of life. The true test of the success of an infant mortality campaign lay not in the reduction of the death rate of babies under one year of age, but in the reduction of the death rate under five years. Practically all of their efforts in the past had been directed against the occurrence of gastrointestinal diseases, with the result that the reduction in the total infant mortality had been almost entirely among diseases of gastrointestinal origin. These now ranked third in the order of importance as a cause of infant deaths. If the infant mortality rate was to be still further reduced, the work of the future must be largely directed against the prevention of the so-called "congenital" causes of death. About 40 per cent. of the deaths during the first month of life were due to conditions affecting the mother before the child was born. Work had been started by the Bureau of Child Hygiene with the object of controlling the conditions affecting the mother during the period of her pregnancy. They had approximately 500 mothers under observation during 1914, with no maternal deaths. Ninety-six per cent. of the babies born were now living. The deaths under one month per 1,000 births were 16, as compared with 37 for the city. The stillbirths in these cases were 17 per 1,000 births, compared with 50 for the city at large. The second important cause of death at this time was comprised in the group classed as "respiratory diseases." Here they had advanced little, if at all, and it was to be hoped that greater progress along this line would be shown in the future. Unless these lines of work were taken up vigorously in the near future it was hardly possible that the infant death rate could be much further reduced. The field for improvement in school medical inspection was so vast that it was scarcely possible to mention any phase of it in the brief time allotted. Present methods had resulted in the practical elimination of contagious eye and skin diseases among public school children. The number of physical defects had been reduced 50 per cent. during the past five years and the system of control of general contagious diseases had been successful in eliminating the widespread epidemics which used to occur in schools. The work of medical inspection of school children had been extended so that each child might be examined by its own physician, if the family preferred, rather than by the school doctor. This undoubtedly would result in a larger number of children being examined and placed under proper care each year. There was one disease of child life that demanded more serious and extended consideration than it had received. Malnutrition in childhood was not only the basis of much ill health in the future, but was becoming more and more prevalent and increasingly difficult to prevent. This was a condition which showed more clearly the social and economic status of the community and of the family than any other one disease that they met, and hence the remedy would probably have to be a widespread one, involving many economic and social problems. It was to be hoped that the work of the bureaus of child hygiene in school medical inspection might become as wholly preventive as it was at present in its effort to reduce infant mortality. The hospitals for the removal of adenoids and enlarged tonsils, as well as corrective dental treatment, did not seem to be the function of the city authority and it was to be hoped that effort would be concentrated on the prevention of these defects rather than their correction. The present dental clinics of the Bureau of Child Hygiene were committed to this policy. Only children between the ages of six and eight years had been cared for. Taken at the time when the first permanent teeth are appearing the mouths had been placed in good condition, the children taught the principles of oral hygiene, and required to report to the dentist every six months thereafter. The results had been encouraging. With clean mouths, future repair work had been reduced to a minimum. If this work could be extended by the employment of dental hygienists, as suggested by Dr. Fones of Bridgeport, Conn., it seemed that they would solve in great part the hitherto insurmountable difficulty of the care of defective teeth in children. In closing Dr. Baker referred to the history of the Bureau of Child Hygiene, which was established only seven years ago, and which, being the first to be organized in the United States, had to establish its own precedents. Whatever success it had achieved had been due to the development of the purely educational phase in public health work, with a gradually increasing cooperation on the part of the public. The full measure of success of preventive and educational public health work could not be achieved without the cooperation of the medical profession.

Increased Responsibility for the Attending Physician.—Dr. L. I. Harris, after referring to the part that the physician had always played by giving of his devoted service and wise counsel for the good of society, declared that every economic, materialistic, and coldly logical argument seemed to show that communities expected too much for too little or nothing from the hard driven physician, yet somehow the memory of fine tradition clung about the practice of medicine and a powerful moral obligation under which the physician rested had dedicated him to service in behalf of the public weal and refuted the strongest of merely logical or economic theories. The failure to give this service had resulted in the appointment of authorized agents who should act as the guardians of public health. But these in their final analysis depended for their effectiveness upon the support which they received from the body of physicians in the community. Each physician who was properly responsive to his moral obligation to the community constituted himself a supplementary or rather a complementary department of health. To this end it would be well to admit physicians to a sort of Associate Membership in public service if their records were not marred by one or more delinquencies. This would necessitate a most thorough and careful investigation with respect to obedience to the Sanitary Code; if a charge of delinquency with respect to the Sanitary Code was established, the Department could with assurance deny the privilege of personal supervision of infectious disease cases to such a private physician. Such a privilege might possibly come to be valued as a badge of distinction and good standing by the profession. Dr. Harris then presented a form of invitation which might serve to show just the kind of plan for cooperation which the Department might extend to physicians. This letter stated that in view of the fact that practising physicians of this city

had at times complained that the activities of the Health Department in the supervision of cases of infectious disease had caused them annoyance and disturbed the harmony of their relations with their patients, the Department of Health offered to concede to the private physician as large a share as possible in the supervision of contagious cases, in accordance with the best tradition and advancing knowledge of the medical art. The signing of the card upon which this invitation was presented would constitute an agreement with the Department of Health and the physician to cooperate. Certain particulars would have to be complied with as heretofore, since the Department must of necessity maintain its statistical record of morbidity and mortality from infectious diseases. The reporting of cases of tuberculosis, major contagious diseases, typhoid fever, and venereal diseases would be required as before by all physicians. By this plan the initial visit of the nurse as well as her subsequent visits would be eliminated. The physician would be held responsible for the prompt forwarding of a history of the case on the blank form provided for the purpose, together with a statement of all the facts needful for public health protection. He would be responsible for the instruction of the family in the requirements of quarantine and isolation. When the physician deemed the case ready for termination, at his request a department representative would make a final visit and determine whether or not quarantine should be discontinued. These final visits by the department representative would continue until such a time as these procedures would have vindicated their value. A similar procedure would be authorized in diphtheria. Measles would be under the complete supervision of the private physician, as would typhoid fever, except in such instances as the physician might request the supervision of the Health Department, because of the patient's financial condition or other sufficient reason. In all these diseases the Department would, however, be able to count upon the physician to furnish all data needed for statistical and general supervisory purposes, and that he should be intermediary between the Department and the patient. This card would also include a description of the duties of the district diagnosticians and an offer that physicians avail themselves of their services, together with a statement that if physicians did not furnish the desired history a district nurse might call for the same. Every "Associate of the Public Health Service" would agree to carry out the above regulations. If such a plan could be proved feasible it would mark a great advance in the administration of public health, and would be beneficial to the physician and to the patient alike. The Department of Health was not ready as yet to stamp this plan with its approval and put it into operation, but if physicians would cooperate along the above described lines the procedure would be safe and sane.

Non-Interference with Immunes.—Dr. L. I. HARRIS presented this paper in which he stated that in diseases whose etiology was baffling and obscure and the subject of speculation, a multitude of remedies was invariably recommended, each of which had its special advocates, who with dogmatic assurance cited their favorite theories in support of their therapeutic agents. Each remedy had its vogue for a time. They were all ultimately discarded when the true cause of such disease was scientifically established. The history of quarantine regulations in infectious diseases had run a parallel course. Until the causative agents in infectious diseases were known numerous procedures for the enforcement of quarantine succeeded each other, each bolstered up by plausible theories and the inevitable and confounding statistical proofs. After giving a number of illustrative instances the speaker said that in most health departments, when cases of measles or scarlet fever had occurred, other children in the family were excluded from school without considering whether they had been made immune to these respective diseases by a previous attack. More and more the necessity and value of this requirement had been challenged. As the result of careful studies and observations carried on by the New York Department of Health in common with others, it had been concluded that immune children should not be subjected to any of the hardships hitherto imposed, but might with safety continue to attend school from their homes, if isolation of the affected individuals was carefully maintained. In the City of Cleveland, liberal regulations regarding this particular subject were in force and immunes were not excluded from school attendance. Detroit, Washington, Omaha and New Orleans had made a timid advance in that direction. These cities placed no restrictions on those immune to measles but required immunes to change their residence in cases of scarlet fever. In view of the careful studies and observations made by a number of progressive sanitaria and in harmony with their conclusions, the New York Department of Health proposed to permit immune children in the homes of scarlet fever and measles cases to continue their attendance at school throughout the period of the disease, if the patient was properly isolated. Under such a plan the question arose as to how such immunes were to be recognized. The unsupported statements of parents or guardians could not be accepted as sufficient to secure the admission of an immune child to school. The Department, therefore, proposed to issue a certificate to each child reported as having suffered from diphtheria or scarlet fever. The certificate would state the name of the disease, the date when it was terminated, and would serve as a passport through the child's school career and later as well. This measure would perhaps tend to make parents feel more kindly disposed towards physicians who desired to report all their cases of contagious diseases to the Department of Health, because of the benefits which would follow from the possession of such certificates. A more general and voluntary compliance by both physicians and parents with the requirements of the Sanitary Code might thus be brought about.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

June, 1914.

(*Continued from page* 378.)

CHEMISTRY.

1. (*a*) State the atomic theory of matter. (*b*) What are ions?
2. (*a*) What is meant by valence? (*b*) Give the valence of the following elements: C, P, O, Mg, I, Cl Hg, S, H, Br.
3. Define and give example of (*a*) a metal. (*b*) a base.
4. Write a formula illustrating the reaction between manganese dioxide and sulphuric acid.
5. What is the most important constituent of Paris green and of Rough-on-rats?
6. Define an alkaloid and name three (3), commonly used in medicine.
7. Of two samples of drinking water, one contains nitrates, with traces of free chlorine; the other contains nitrites and free chlorine; which is the safer for drinking purposes? Why?
8. (*a*) What is the significance of lactic acid in stomach contents. (*b*) Describe a method of detecting the presence of lactic acid.
9. Describe in detail a method of examining urine for bile.
10. Discuss proteins.

MATERIA MEDICA.

1. Discuss briefly the vaccine and serum theories. Give examples with mode of administration and state for what conditions used.
2. Boric, tannic, dilute hydrochloric, nitric and salicylic acids: Describe and give doses, using official term.
3. Nitrate of silver, arsenic, male fern, aspirin: Give official preparation and doses.
4. Define physiological effect, toxicology, incompatibility, idiosyncrasy and cumulative effect.
5. Cannabis indica and aconite—the part of the plant used—preparations and doses.
6. Give the average adult dose of extract of opium, brown mixture, fluid extract colchicum, tincture digitalis, potassium iodide, tincture nux-vomica, fluid extract ergot, syrup iodide of iron, Fowler's solution of arsenic and Donovan's solution. Give preparation and doses, using official terms.
7. Cocaine, codeine and creosote: The official preparations and doses.
8. Write a prescription, for 36 pills, of iron, arsenic, strychnine, quinine and gentian, to be given at each meal, for an adult.

9. Ether, tartar emetic and antipyrin: The official preparations and doses.

10. Describe and give doses of acetanilid, amyl nitrite, and caffeine.

THERAPEUTICS.

1. Write a prescription in Latin, without abbreviation, containing a heart sedative and diaphoretic, stating the condition for which it is to be used, with direction for administration.

2. Give the therapy of belladonna, symptoms of poisoning and treatment.

3. Give indications for, and restrictions in, use of chloride of sodium.

4. Give the therapy of quinia, dose and period of administration for special conditions.

5. Give the therapeutic uses of the hypophysis or pituitary body.

6. Give the therapy of ipecac, name and special use of its active principle.

7. Give the name and special use of the active principle of the suprarenal glands.

8. Give the therapy of strychnia, symptoms of poisoning and treatment.

9. Differentiate the therapy of aconite and veratrum viride.

10. Give the physiological action and therapy of bromides.

ANSWERS.

CHEMISTRY.

1. *The atomic theory*, put forth in modern times by Dalton in 1807, is based on ideas held by the Greek philosopher, Democritus, viz., that matter is not infinitely divisible, but that atoms of varied shapes and all in rapid motion are the ultimate division. Dalton rendered the idea more precise by ascribing to these atoms real magnitude, and a definite weight, and by considering elementary substances as made up of atoms of the same kind, and compounds as consisting of atoms of different kinds.

Ions are the primary constituents of salts which are separated from each other during electrolysis.

2. *Valence* is the combining or replacing power of an atom of an element compared with that of an atom of hydrogen.

The valence of carbon is 4; of phosphorus, 3 or 5; of oxygen, 2; of magnesium, 2; of iodine, 1; of chlorine, 1; of mercury, 2; of sulphur, 2; of hydrogen, 1; of bromine, 1.

3. A *metal* is an element which is capable of replacing the hydrogen of an oxyacid to form a salt.

A *base* is a ternary compound which is capable of entering into double decomposition with an acid to form a salt and water.

4. $MnO_2 + H_2SO_4 = MnSO_4 + H_2O_2$.

5. The most important constituent of Paris green is arsenic; of rough-on-rats, is phosphorus.

6. An *alkaloid* is a nitrogenous organic substance, of alkaline reaction, and capable of combining with acids to form salts in the same way that ammonia does. *Three alkaloids commonly used in medicine:* Strychnine, morphine, and quinine.

7. The former of the two samples is probably the safer, because (1) chlorine is only present in minute amount, and may have come from the sea; and (2) because nitrates are not the same indication of recent contamination with sewage as nitrites; the presence of the latter is always suspicious.

8. *Lactic acid* is formed in the stomach during the digestion of carbohydrates. Pathologically, it is believed to indicate cancer of the stomach.

The *presence of lactic acid* is detected by Uffelmann's reagent, which consists of a solution of Fe.Cl, and phenol, diluted to an amethyst-blue color, which is changed to yellow by lactic acid.

9. *Gmelin's test for bile-pigments in the urine:* "This consists in bringing slightly yellow nitric acid into contact with the urine. A play of colors, of which green and violet are most distinctive, denotes the presence of bile-pigment. Colorless nitric acid will become yellow upon standing in the sunlight. The test may be applied in various ways: by overlaying the acid with the urine; by bringing a drop of each together upon a porcelain plate; by filtering the urine through thick filter-paper, and touching the paper with a drop of the acid; and, probably best of all, by precipitating with lime-water, filtering, and touching the precipitate with a drop of the acid. In the last method bilirubin is carried down as an insoluble calcium compound."—(Todd's *Clinical Diagnosis.*)

10. "*Proteins* are never absent from living animal or vegetable cells, to whose 'life' they are indispensable. They are almost all uncrystallizable, and only slightly dialyzable. Some are soluble in pure water, others only in the presence of other substances, and others are insoluble in water. They are insoluble in alcohol, ether, chloroform or benzene. They are composed of carbon, hydrogen, oxygen, and nitrogen. Most of them also contain sulphur, and some contain phosphorus; others, iron, copper or iodine. Their molecular weights are very large, probably greater than 10,000. Their constitution is unknown, and no substance has as yet been obtained synthetically which is identical with a natural protein, although substances have been thus produced having many of the properties of gelatins or albumoses."—(Witthaus' *Essentials of Chemistry.*)

MATERIA MEDICA

1. "A *serum* is a product obtained by injecting into an animal, usually the horse, a culture (*e.g.* Diphtheria) or the toxin from a culture (*e.g.* Streptococcus) of the organism. Serums may be subdivided into—(a) *Antitoxic serums*, such as Diphtheria and Tetanus, which are obtained by injecting filtered cultures into the animal used to provide the serum. (b) *Anti-bacterial serums*, such as Anti-Streptococcus and Anti-Gonococcus, in the preparation of which unfiltered cultures are used. Serums are usually injected in the flank or between the shoulder blades, the skin having previously been cleansed and the syringe carefully sterilized. Cases are on record where they have been given intravenously with normal saline solution and also per rectum.

"A *vaccine* is a finely divided suspension of killed cultures of a microorganism which is injected directly into the human subject. The object is to stimulate the individual to elaborate his own antibodies, which results in increased resistance to the ravages of bacterial infection. Vaccines are of two kinds—(a) *Autogenous*—prepared from the organism isolated from pathological material taken from the patient. (b) *Stock* prepared from virulent cultures of the organism, isolated from other cases of similar bacterial origin. Vaccines are administered by subcutaneous injection by means of an all-glass hypodermic syringe. The site of injection may be the flank, thigh, shoulder, or back. The skin is first sterilized by a pledget of cotton wool saturated with a suitable antiseptic, *e.g.* lysol.

"Briefly, the difference is that with a serum the opposing influence to the toxins is produced outside the human body, while with the vaccine it is produced inside and the degree of immunity conferred is greater with the latter than the former. It should also be noted that the dose of a serum is much higher, from the standpoint of the amount of fluid injected, than in the case of a vaccine. With the former the dose usually ranges from 10 c.c. to 50 c.c., while with the latter it is, as a rule, not more than 1 c.c." (*Holland's Pharmacy Handbook.*)

2. *Acidum boricum* consists of transparent, colorless scales, or crystals, or a fine powder; it is sticky to the touch, odorless, slightly soluble in water and in alcohol; average dose, gr. vijss.

Acidum tannicum is a light yellowish amorphous powder, with little or no odor and an astringent taste; moderately soluble in water and in alcohol; freely soluble in boiling water or alcohol; average dose, gr. vijss.

Acidum hydrochloricum dilutum should contain 10 per cent. of absolute hydrochloric acid and 90 per cent. of water; average dose ♏ xv.

Acidum nitricum should contain 68 per cent. by weight of absolute nitric acid and 32 per cent. of water; it is a colorless, fuming liquid, very corrosive and caustic, and with a peculiar suffocating odor.

Acidum salicylicum occurs as fine white needles or a crystalline powder; the taste is first sweetish then acid; readily soluble in boiling water, but very sparingly soluble in cold water; average dose, gr. vijss.

3. Argenti nitras, gr. 1/5; argenti nitras fusus; argenti nitras mitigatus.

Arseni iodidum, gr. 1/10; arseni trioxidum, gr. 1/30.

Aspidium, gr. lx; oleoresina aspidii, gr. xxx.

Aspirin is not official.

4. *The physiological effect of a drug* is its action on a healthy person.

Toxicology is the branch of science which deals with poisons, their effects, antidotes, detection, etc.

Incompatibility is the condition which results when

substances are prescribed together which are not miscible without chemical change or which are antagonistic.

Idiosyncrasy is a peculiarity in a person which makes him react to drugs in a manner different from most other persons.

Cumulative effect is the marked effect produced after the administration of a number of doses which have each produced little or no effect.

5. *Cannabis Indica:* The dried flowering tops of the plants of *Cannabis sativa* are used; preparations are: the extract, gr. 1/5; fluid extract, ♏ ij, and tincture, ♏ x.

Aconite: The part used is the dried tuberous root of *Aconitum napellus;* preparations are: the tincture, ♏ x, and fluid extract, ♏ j.

6. Extractum opii, gr. ½; Mistura glycyrrhiza composita, ʒ ij; Fluid extractum cholchici seminis, ♏ iij; Tinctura digitalis, ♏ xv; Potassii iodidum, gr. vijss; Tinctura nucis vomica, ♏ x; Fluidextractum ergotæ, ♏ xxx; Syrupus ferri iodidi, ♏ xv; Liquor potassii arsenitis, ♏ iij; Liquor arseni et hydrargyri iodidi, ♏ jss.

7. *Cocaine:* The hydrochloride, gr. ½; oleate.

Codeine: The phosphate, gr. ½; sulphate, gr. ½.

Creosote: Aqua creosoti, ʒ ij.

8. ℞ Ferri reducti gr. xxx.
Arseni trioxidi gr. j.
Strychininæ sulphatis gr. ss.
Quininæ sulphatis gr. xxx.
Extracti gentianæ ʒ j. Misce.
Fiat massa in pilulas No. xxxvj dividenda.
Signa: Take one at each meal.

9. *Ether:* Oleum æthereum; Spiritus ætheris compositus, ʒ j; Spiritus ætheris nitrosi, ♏ xxx.

Tartar emetic: Antimonii et potassii tartras, gr. 1/10, expectorant; gr. ½, emetic. Vinum antimonii, ♏ xv; Syrupus scillæ compositus, ♏ xxx.

Antipyrin: Antipyrina, gr. iv.

10. *Acetanilid:* A crystalline powder, odorless, with a sharp taste, slightly soluble in water, soluble in boiling alcohol, dose gr. iv.

Amyl nitrite: A clear, yellowish liquid, with a ungent taste and a peculiar fruity odor, almost insoluble in water; dose ♏ iij.

Caffeine: White, silky needles, with a bitter taste, no odor, very slightly soluble; dose gr. j.

THERAPEUTICS.

1. ℞. Extracti aconiti gr. ij.
Pulveris ipecacuanhæ et opii gr. xij.
Phenacetin gr. lx.
Quininæ sulphatis gr. xxiv.
Misce, et fiat in capsulas No. xxiv.
Signa: Take two every three hours.
For influenza.

2. Belladonna.—*Therapeutic indications:* To relieve pain, relax spasm, check sweating, as a mydriatic for night sweats, to check griping of purgative; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, spasmodic cough.

Symptoms of belladonna poisoning: "In the first stage, that of delirium, there are dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely-dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration." (Witthaus.)

Treatment: The stomach should be washed out; pilocarpine, may be given hypodermatically; morphine may be given cautiously during the period of violent excitement; cold applications to the head and artificial respiration are useful. There is no chemical antidote.

3. *Uses of sodium chloride:* "Locally it is of service in affections of the mucous membranes, and salt baths are invigorating as well as cleansing. A strong solution constitutes one of the best injections for thread-worms, and salt solutions are also used to limit the action of silver nitrate. Hot salt, enclosed in bags, is a good application in lumbago and various other painful conditions. Internally, as an emetic and also in dyspeptic conditions, administered in carbon dioxide water or in the form of natural mineral waters. Solutions of salt in distilled water are given by intravenous injection or hypodermatoclysis in conditions where the body has lost much fluid, and also in carbon dioxide or coal gas poisoning and in uremia and similar intoxications. In poisoning by silver nitrate sodium chloride arrests the corrosive action."—(Wilcox's *Materia Medica.*) Concentrated solutions should not be used as enemas, as they have caused death in some instances; only isotonic solutions should be used.

4. "*Quinine* is employed locally for unhealthy sores and infected wounds, diphtheria, otorrhea, whooping-cough, hay-fever, gonorrhea, chancroids, and chronic cystitis. The preparations of cinchona are given in digestive troubles, especially when these are associated with a debilitated state of the system. Quinine is one of the most commonly used of all tonics. Except in the case of malarial fever, it is now comparatively seldom employed as an antipyretic. One of the most positive effects in the whole range of medicine is that of quinine, and to a less pronounced degree of other alkaloids of cinchona, in arresting the paroxysms of malarial fever; it is now known that this result is due to the directly poisonous action of the drug upon the *plasmodium malariæ*, which infests the blood and is the specific cause of the disease. It is both curative and prophylactic; so that is regular administration in very moderate quantities will absolutely or to a large degree protect persons living in malarious regions from ague. Quinine is used in malarial neuralgia and also in neuralgias not of malarial origin. Among other affections in which it is employed internally also may be mentioned whooping-cough, influenza, the night-sweats of phthisis, the adynamic form of delirium tremens, and various conditions associated with cerebral anemia."—(Wilcox's *Materia Medica.*) In malaria, fifteen grains should be administered at the time of the chill.

5. "*Pituitary extract*, containing the principle found in the posterior lobe which acts on unstriped muscle, is now an ordinary article of commerce for many therapeutic purposes. It is a favorite remedy for surgical and toxemic shock, and many observers are convinced that it does good by raising the blood-pressure. A very valuable effect is that it promotes peristalsis even when purgatives fail or are vomited. . . . A third indication is to increase labor pains; sometimes in cases of weak pains the child is expelled very rapidly after an injection. It is a powerful diuretic. As a galactagogue its success so far has been doubtful. Feeding with the gland may be valuable in some forms of amenorrhea. Pituitary extract must not be given frequently at short intervals, or its effect may be reversed."—(Short's *Newer Physiology.*)

6. *Therapy of ipecac:* "It is used as an emetic, especially for the purpose of clearing the passages in diseases of the respiratory organs and for relieving the stomach of undigested food; in small doses as a stomachic and to check vomiting; dysentery; catarrhal jaundice; diarrhea, especially when associated with hepatic derangement; bronchitis, winter cough, emphysema and fibroid phthisis; as a diaphoretic in acute rheumatism, suppression of menstruation, chills, and the early stages of catarrh of the respiratory passage and of mild feverish attacks in general; hemoptysis and other hemorrhages."—(Wilcox's *Materia Medica.*) The active principle is emetine, which has a specific action in amebic dysentery.

7. The active principle of the suprarenal glands is known as epinephrin. It is used as a local vasoconstrictor, to check hemorrhage, to prolong local anesthesia, to overcome shock, and to relieve congestion.

8. Strychnine. *Therapeutic indications:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

Symptoms of poisoning: "A sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours.

"*Treatment:* The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

9. "*Veratrum viride* may be employed for the same conditions for which aconite is recommended, although it is doubtful whether it possesses any advantages over the latter drug; indeed, by many competent physicians it is considered inferior to, and more dangerous than, aconite. Moreover, the nausea and vomiting which in many patients are likely to follow the ingestion of this drug render its use objectionable. A large number of physicians claim to have found it of value in the treatment of puerperal eclampsia. Here it should be given in doses sufficient to cause nausea or even vomiting."—(Butler's *Materia Medica.*)

10. Bromides. *Physiological action:* "The bromides in concentrated solution are gastrointestinal irritants. They are directly depressant to the cerebrospinal axis, producing lassitude, drowsiness, and sleep (which, however, is never very deep), with marked diminution of reflex irritability and of the respiratory and sexual functions. They are diuretic, especially the lithium salt, and are excreted mainly in the urine, but to some extent also in the perspiration and milk and probably by the bronchial and intestinal mucous membrane. Potassium bromide weakens the heart's action and is also more depressing to the central nervous system than the others. Lithium bromide is the richest in bromine and is thought to have the most pronounced hypnotic effect. The strontium and calcium salts are said to produce less digestive disturbance than those of the alkalies, but they appear to be absorbed more slowly. In bromism, or chronic poisoning, there are acne or other skin eruptions, a catarrhal condition of the mucous membranes, derangement of digestion, diminished sensibility, especially of the faucial mucous membrane, uncertain gait, dulled intellect, impairment of memory, and an apathetic expression of countenance.

"*Uses:* The bromides constitute our most valuable remedy for epilepsy, but as they must be continued for a long period, every effort should be made to minimize their injurious effects upon the system. They are much used also, either alone or in combination with other drugs, in the treatment of insomnia, nervousness, hysteria, neuralgia, migraine, delirium tremens, seasickness, seminal emissions, nymphomania, and various forms of convulsions. Except in cases of epilepsy they should not, as a rule, be given continuously very long, on account of the danger of the patient's contracting the bromide habit."—(Wilcox's *Materia Medica.*)

Miscellany.

To Deaden the Sound of War.—According to *The Sun,* an interesting invention which has just been adopted by the British Admiralty is the Mallock-Armstrong ear defender. The earpiece is no larger than the cotton-wool plugs hitherto used, but contains a diaphragm of goldbeater's skin, which, while readily responsive to ordinary volumes of sound, muffles any abnormal sound. This effect is brought about by a "stop" which limits the distance through which the diaphragm can vibrate. While the ear receives readily and clearly a word of command, it is protected from the noise of the discharge of a gun.

The Founder of Modern Public Health Science.—A keen observer, excellent technician, thorough, methodical and painstaking in his work, the subject of this sketch shares with Pasteur the honor of founding bacteriology and establishing the relation of bacteria to disease. To him we owe the introduction of solid media as a means of isolating bacteria in pure cultures—an advance which made bacteriology a really practicable science. His strictly logical mind conceived and formulated a set of postulates to be complied with before a microorganism could be regarded as the cause of a particular disease. The beneficent influence which these have exercised on medical science during the past thirty years can hardly be overestimated. His discovery of the bacillus of tuberculosis gave us the first real hold on one of mankind's chief scourges; even his celebrated London address concerning the role of bovine tuberculosis did excellent service by restoring our sense of proportion. His brilliant work in tracing the transmission of cholera revolutionized the method of combating infectious diseases. Throughout life, proud that he had been a practising physician, and striving always to make his work practically useful, we honor Robert Koch above all as the great practical sanitarian and founder of modern public health science.—*Weekly Bulletin of the Department of Health of the City of New York.*

Dangers of the Wrist Watch in Warfare.—Not only German officers but some of the rank and file as well make considerable use of the wrist watch in warfare, wearing it on the left wrist, despite the fact that the left hand and forearm are very frequently hit by infantry bullets as a result of their exposed position. The effect of the high velocity of the projectiles when they chance to strike the watch fairly is to shatter it into unrecognizable fragments, many of which are driven directly into the carpal bones and the contiguous bases of the metacarpals and head of the radius. The wrist bones are laid bare, and the thumb may be nearly shot away. Some of the bones are rendered necrotic and a putrescent discharge escapes. In the *Berliner klinische Wochenschrift* for December 28, Melchior reports his second case of this type. There was a marked local reaction, the entire forearm swelling greatly, while a gas phlegmon formed between the muscles. The patient developed general sepsis. The damage done to the arm by these injuries is so radical that no treatment can restore to the patient the industrial use of his arm, although prompt and radical measures should save life and render amputation unnecessary. So many injuries of this kind have been reported that the use of the wrist watch in the army will doubtless soon be prohibited, if this precaution has not already been taken.

HISTORY OF THE PATHOLOGICAL PHYSIOLOGY OF ICTERUS.*

BY CHARLES GREENE CUMSTON, M.D.,

GENEVA, SWITZERLAND.

PRIVAT DOCENT OF THE HISTORY OF MEDICINE AT THE FACULTY OF MEDICINE OF THE UNIVERSITY OF GENEVA; FELLOW OF THE ROYAL SOCIETY OF MEDICINE (LOND.); MEMBER OF THE MEDICAL HISTORICAL SOCIETY OF FRANCE, HISTORICAL SOCIETY OF GENEVA, ETC.

ALTHOUGH this subject has been scientifically investigated only during the last twenty years, the study of the syndrome icterus and its pathogenesis is none the less one of the old pathological problems. The ancients had far too incomplete a knowledge relative to the chemistry of the bile and physiology to have been able to conceive the slightest notion as to the exact pathogenesis of icterus. They included in a confused and indefinite symptomatic ensemble various morbid conditions comprising icterus, gastric symptoms dependent on the liver, changes in the blood, the bile, or the humors, and looked upon them all as bilious conditions.

Hippocrates considered the bile as one of the principal humors of the body, while the Arabs enumerated the various aspects that it may present. In the XVI century, the pathogenic part played by the bile was doubted by Paracelsus and Van Helmont. For the former, it was merely a foreign substance, while the latter looked upon it as a fluid elaborated by the better part of the blood, the balsam of the blood as he expressed it, and could not cause any disease. The morbid bilious states were at this period conceived to be due to disturbances of the digestion, and here we have the gastric theory of bilious pathology. Sylvius attributed an important pathogenic rôle to the bile, a product of dangerous fermentation, but he has furnished no proof in support of his hypothesis.

Thanks to the studies in the domain of anatomy, the notion of icterus finally acquired some precision. The first notion of biliary retention in the blood by the suppression of the hepatic functions is undoubtedly due to Morgagni in the 37th letter of his "Epistolarum anatomicarum," and it may be unreservedly admitted that this is the starting-point of the interpretation of icterus from the viewpoint of mechanical causes. Glisson, in his "Anatomia hepatis," published in 1659, emitted the opinion that the liver is simply a reservoir for the bile furnished by the blood, and he considers icterus and bilious conditions as due to the absence of hepatic secretions. Boerhaave, in the fifth volume of his "Praxis medica" and Van Swieten in his "Commentarii in Boerhaavii Aphorisma" (1769) later adopted this opinion. But soon other writers, Munro for example, also Werlhoff and Selle, looked upon the cause of icterus as merely a disturbance of excretion. At this period, two doctrines were apparently in vogue, namely, that of icterus from defective secretion and that of icterus from faulty excretion.

It would appear quite natural that a new hypothesis should be derived from the first theory. The bile, not being the product of the liver but simply extracted by it, since it was formed in the blood, the interference of the hepatic gland did not appear essential for the development of icterus, the blood itself transforming into bile, and here arises the theory of hematic icterus. In 1725, Bianchi, in his "Historia hepatica," attributes icterus to a too rapid dissolution of the red blood corpuscles, which he describes as follows: "Sunt duo primaria icteri genera; primoe classis icterus e vitio hepatis, alterius speciei icteri a causa solutiva sanguinis." Some fifty years later, Reil, in his "Tractatus de polycholia," published in 1782, described cases of icterus with colored feces and without biliary occlusion, and upheld that the polycholia was due to an abnormal bile resulting from the direct transformation of the blood and this bile entering the intestine would produce disorders which in turn would give rise to the bilious affection. Grant, in his "Observations on Fever," Vol. I, gives the name of biliary juice to the yellow portion of the blood-serum and attributes the cause of icterus to an increase and change of this juice resulting from the action of the hepatic gland. At the same time when the theory of hematic icterus seemed to become clearly established, Saunders, in his "Treatise on the Structure, Economy and Diseases of the Liver," 1795, by ligature of the ductus cholodochus which he undertook for the first time in the history of medicine, placed icterus from retention and absorption upon a firm experimental basis. In 1803, Deyeux in his "Considérations chimiques sur le sang des ictériques," indicates that the true solution of certain cases of icterus must be looked for in the clinical examination of the humors and, upholding that it is quite impossible to find bile in the serum of newly born icteric infants, he appears from this statement to emit the hypothesis of pigments of another nature being able to produce icterus.

A century after Bianchi, Breschet, in 1821, believed that the pigment was the product of the red blood corpuscle and he says that he surmises that icterus is far less likely to be the product of the bile than of the blood. Dubreuil, in 1826, accepted this opinion after making autopsies on subjects dying with icterus without being able to discover any obstacle to the flow of bile. Virchow, in 1847, likewise Zencker and Funke, adopted this new theory. Studying the icterus of the newly born, Virchow found uratic infarcts in the kidneys, pale

*Inaugural lecture to the winter course of the History of Medicine, delivered at the Faculty of Medicine of the University of Geneva, October 30, 1914.

reddish colored streaks with he believed to be composed of hematoïdin, the crystals of which he found in the renal substance and stained the cells of the renal epithelium. Nine years later, he gave up this theory. Zencker and Funke, demonstrating that the coloring substances of the bile can produce crystals like hematoïdin, questioned whether or not certain substances derived from the blood could not give rise to the yellow tint of the integuments.

Now, just at this epoch, Frerichs exposed a new theory, that of biliary acids. Basing his opinion on the following facts, namely, that certain chemical reactions transform the biliary salts into bile pigment and that the intravenous injection of large quantities of biliary acids into a dog is followed by the presence of bile pigment in the urine, he admits that an hematogenous icterus can be produced by the bile pigments. These represent the intermediary product of the process of oxidation of the biliary acids introduced into the circulation by intestinal absorption, normally giving rise to chromogenous substances which, passing through the stages of intermediary products, are eliminated in the form of urinary pigments. This elimination of bile pigments takes place when the quantity of biliary acids absorbed by the intestine is too great (polycholia) or when the process of oxidation is insufficient. In other words, we here have a theory analogous to that of diabetes mellitus from insufficiency in the metabolism of sugar.

It was not long before this theory was opposed by various writers, particularly by Kühne in 1858, whose hypothesis which is to follow, rapidly caused that of Frerichs to be forgotten. Admitting the intestinal absorption of biliary acids, Kühne rejected the hypothesis of their direct transformation into pigment. According to his way of thinking, they exercise a dissolving action on the red blood corpuscles, so that the coloring matter of the blood, hemoglobin, is liberated and is dissolved in the blood-serum and becomes transformed into pile pigment. Thus is explained the presence of hemoglobin in the urine before its transformation into the coloring matter of the bile.

While one dared to look to hematology and biological chemistry in the attempt to solve the problem of the pathogenesis of the syndrome icterus, which appeared to present many difficulties, Gubler, in 1857, summed up the then reigning condition of the question and finally exposed his remarkable theory of hemapheic icterus. He was of the opinion that jaundice was due to two causes, for the very good reason that there are cases in which the biliary ducts are obstructed and others in which they are completely patent. The first class of cases does not appear difficult to explain: a biliary retention due to some obstruction of the biliary tract, the bile no longer being able to flow off by way of the usual routes into the intestine, is absorbed and enters the circulation. It then impregnates the tissues, staining them yellow, and enters into the principal fluids of the body, the urine in particular, in which it can be detected by appropriate means. This first class composes the type of bilipheic icterus.

The second class is not so easily explained. It comprises numerous cases accompanied by severe blood disturbances. The excretory biliary passages are patent because the feces remain colored by the bile, but in spite of this the patients present an icterus. If the bile pigments are searched for in the urine they are found absent, and, nevertheless, the urine is dark colored, this being attributed to the presence of an undetermined body. This body which is derived from the blood is termed hemaphein. The urine is termed hemapheic and in no way resembles that of bilipheic icterus. Hemapheic urine is of a red amber color going to dark red, and can be compared in hue to certain strong English beers or a concentrated decoction of tea. Bilipheic urine has a greenish yellow hue with a greenish reflexion, and by shaking gives rise to a persistent greenish froth. Hemapheic urine stains linen a salmon-pink color, while the bilipheic type colors it a greenish yellow. Treated with nitric acid hemapheic urine takes on an obscure reddish brown tint, similar to mahogany, while bilipheic urine is green.

And lastly, hemapheic urine does not give rise to a resinoid precipitate soluble in alcohol, as is the case with bilipheic urine.

Such are the physical and chemical characters constantly and absolutely characteristic of Prof. Gubler's hemapheic urine. And in order to be in accord with the ideas at that time admitted, he insisted that the bile pigments originate from the coloring matter of the blood, the transformation taking place in the liver, while according to his way of thinking, the bile was only a waste product. But if under some influence producing an intense globular destruction, the liver can no longer suffice to eliminate this coloring matter, the latter instead of being transformed by the hepatic gland into bile pigment, is carried in a modified form into the circulation and produces a yellow staining of the tissues, from which arises the name of hemapheic icterus.

At the same period, Niemeyer in 1855, pretended that the changed bile pigments derived from hemoglobin, might very well circulate in the blood. Bamberger, in the same year, even went so far as to uphold that jaundice is not always due to bilirubin and that the tissues may be impregnated by a pigment intermediary between biliphein and hemoglobin. In 1862, Budd and Harley put forward the idea that the blood itself contained the elements of the bile. When the liver, for some reason or other, can no longer functionate and thus separate the bile from the blood, the latter deposits the more or less changed elements in the tissues and fluids of the body. This theory which admitted that the bile was preformed in the blood and, consequently, denied the part played by the liver in biligenesis, did not subsist for any length of time, because as far back as 1850, Müller and Kunde, by extirpation of frogs' livers, had proven that this was not followed by an accumulation of biliary matter in the blood.

In 1866, Leyden admitted that various substances have a dissolving action on the red blood corpuscles, phosphoric acid and distilled water for example, so that hematogenous icterus might very properly be engendered by different substances producing hematolysis and the analysis of the urine would differentiate hepatogenous icterus from hematogenous icterus, by showing in the former the presence, and in the latter, the absence of bile acids. This theory was not long in being attacked and in 1868, Naunyn repeated the experiments of Leyden. Submitting animals to the inhalation of arseniated hydrogen or injecting them with bile acids, ether or chloroform, he obtained very different results; occasionally bile pigments in very small amount. He based his conjectures on the fact that injection of bile acids into the intestine causes bile acids and

coloring matter of the bile to appear in the urine and that intestinal absorption in the genesis of icterus implies an interference on the part of the liver in the formation of this pigment.

Neumann, in 1868, recorded the autopsy of an infant who died from icterus two days after birth and stated that he found uratic collections in the kidneys and yellow tinted crystals in other viscera. The fat-globules of the cellular tissue also presented a light red tint with pigmented crystals. In 1873, Primavera described an imperfect bile pigment which he looked upon as hemaphein. Parrot and Robin also found yellow corpuscles in the urine of newly born icteric infants, which did not give rise to the reaction of bilirubin, and which in their turn, they considered as hemaphein. Identical results were also mentioned by Krebs and Orth in 1875. In a word, all writers found altered blood pigment and called it bilirubin, others hematoidin, still others hemaphein, and with all these researches the problem of the transformation of the coloring matter of the blood remained thus: does it take place in the blood itself as Kühne and Leyden believe, or in the liver as taught by Naunyn?

For many, there was one point which had been demonstrated, namely, the increase of the bile pigment, from the fact that the coloring matter was in the circulation. In 1882, Stadelmann endeavored to confirm these facts. After having injected animals with hemoglobin, he noted a marked increase of the bile pigment, and what is more, noting that after the injection the amount of bile decreased, that it became thickened, viscous and flowed with difficulty through the ducts, he thought that from all these phenomena he had found the explanation of the so-called hematogenous icterus, which arises when a slight obstacle or an individual disposition hinders more completely the biliary excretion, and is followed by absorption. According to this writer, the liver transforms the hemoglobin into bilirubin. In the explanation of the mechanism of icterus produced by the introduction of foreign substances into the blood, toluylenediamine for example, not noting any dissolution of the red blood corpuscles and finding at autopsy an icteric liver, he concluded that it is an icterus of hepatic origin resulting from a polycholia and an intense thickening of the biliary fluid.

Ajanassiew, in the following year, showed that this theory can not explain the hemoglobinuria which takes place in some cases after the introduction of foreign substances into the circulation. He admits the destruction of the red blood corpuscles and then separation into granulations. When they become fragmented in the serum without dissolving, the liver transforms them into bile pigment and an icterus results. When in the serum, besides the fragmentation there is dissolution, the serum becomes colored and an hemoglobinuria is produced. When the destruction is considerable hemoglobinuria and icterus are produced.

Stadelmann soon put forward these new conceptions and at the same period, Ponfick examined cases of icterus occurring after the ingestion of a toxic species of mushroom and observed a rapid dissolution of the red blood corpuscles and a diffusion of the coloring matter in the blood-serum. Noting an icterus and an increase of the biliary excretion following upon a hemoglobinuria, he appears to admit Stadelmann's theory. It would seem that at this time the dissolution of the red blood corpuscles was admitted to be the cause of the icterus, but it was a question whether or not it was the dissolved hemoglobin which served, by the intermediary of the liver, for the elaboration of the bile pigment; also whether or not the polycholia following a hemoglobinuria or the action of toxins gave rise to the icterus, consequently, new theories were not long in making their appearance.

In 1874 Poncet stated in his thesis on hematic icterus of traumatic origin, that it was the result of changes undergone by the hemoglobin of the blood extravasations which had undergone absorption. Later, in 1887, these facts were confirmed by Gerhardt, who in turn, took them up and remarked that Gmelin's reaction was absent in the urine of certain icteric patients and that the presence of urobilin was distinctly evident, and with Kunkel he put forward the theory of urobilinic icterus.

Although Bergmann and Dick had demonstrated the increase in the quantity of urobilin in the urine after the absorption of extravasated blood and that Hoppe-Seyler and Maly had obtained urobilin, the former by reduction of the hemoglobin, the latter by reduction of the bilirubin, admitting in the cases of icterus in the tissues or intestine, this theory of icterus from urobilin was not long in being defied.

Quincke, Kiener, and Engel were unable to discover urobilin in the tissues and after the very small amount revealed in the fluids of icteric subjects which, freed from bile pigments, were only slightly tinted, were unable to admit that the urobilin possessed a coloring power sufficient to produce icterus. This formation of urobilin was, according to Kiener and Engel, the most advantageous process possessed by the body to rid itself of the hemoglobin and bile pigments accumulated in the tissues and, on account of the great diffusible power of urobilin, this would be rapidly eliminated by the urine. The doctrine of hematogenous icterus would seem, consequently, according to such opinion, to lose ground, and by the construction of various theories, an attempt was made to give some part in the process to the hepatic gland. Thus, Kiener admitted that in icterus from poisoning by toluylenediamine, a stasis exists in the hepatic lobules. "The most frequent cause of this stasis, leaving aside occlusion of the larger biliary ducts which is not common, is the thickening of the bile which has become exceedingly rich in coloring matter. It is in the hepatic lobule itself, in MacGillavry's canalicules, that the flow is hindered. The cause of the thickening of the bile is the superabundance of the coloring matter of the blood whose transformation into bilirubin is performed by the liver. This superabundance is absolute when there is an exaggerated destruction of the red blood corpuscles; it is relative when the hepatic parenchyma is partially destroyed, as in cirrhosis."

In 1892, falling in with Minkowski's idea, icterus was considered due to a functional disturbance of the hepatic cells, which was unable to get rid of the products of its functional activity by the normal ways of elimination. This is the *icterus by diffusion*. Liebermeister, in 1893, admitted that the altered hepatic cell could not retain the bile elaborated and allowed it to enter the circulation. This is the so-called *acathectic icterus*. All these theories could, consequently, serve at this time to justify the words of Vulpian, who said: "The existence of hematogenous icterus appears as yet to have to be entirely proven."

It was at this time also, that no doubt appeared to exist as to the pathogenesis of the so-called icterus from retention, at least in general, all researches being directed to those instances of jaundice where the biliary tract was patent and the bile pigments were absent in the urine. From 1897, numerous publications appeared up to the appearance of Leuret's thesis, describing this special syndrome, which was termed *acholuric icterus*.

Hyem, in May, 1897, was the first to draw attention to this syndrome. He describes a chronic acholuric icterus without urobilinuria. In this class are placed those states in which the normal bile pigments, or those having undergone some change, contained in the blood are not eliminated by the urine. In the same year, Hyem and Ghicka described a case of acholuric icterus without urobilinuria (acholemic) but in which they found in the blood-serum and urine the typical spectrum of methemoglobin. The stools having become hypercholic and the bilirubin having appeared in the urine shortly before the patient's death, they termed this a case of hematic icterus from methemoglobinemia, *hematohematogenous icterus*.

Now just here a discussion comes up and a most important problem offers itself, viz.: Can an icterus be produced by other pigments than the normal bile pigments? The above-mentioned case would seem to indicate that this is probable and Hyem said: "Between true icterus and pure urobilinuria, there is a large place for numerous intermediary conditions which find their explanation in the phenomena of oxidation and reduction which the coloring matters derived from hemoglobin undergo." The badly defined modified pigments, particularly the reddish-brown pigment, responding to the characters attributed to hemaphein, giving in the urine a reaction other than Gmelin's classical one, and others comprised between bilirubin and urobilin, are quite capable of giving rise to icterus. This opinion was abandoned by Hyem in 1899, after having been opposed at this epoch by various writers who upheld that alone the normal pigment could produce icterus. And nevertheless, Gilbert and Castaigne (1899) were unable to obtain Gmelin's reaction of normal pigments in the blood-serum of certain cases of icterus. Considering that urobilin has no tinctorial power whatever, they believed that the abnormal pigments, particularly the reddish-brown pigment, although it is a badly defined body, is capable of producing icterus.

In his thesis on acholuric icterus, Borrell, in 1899, desirous of establishing the reality of this process, undertook a very profound study and research for the true bile pigments comparatively in the urine and blood-serum. He concludes that in the urine Gmelin's reaction gives the best results. The spectroscopic examination may likewise be used, showing an extinction of the right side of the spectrum, reaction due, according to Borrell, to the yellow coloring property of the bile pigments. To detect the bile pigments in the blood-serum, he used Gmelin's reagent by Lenoble's method, placing with a pipette two or three drops of serum in contact with nitric acid, which became solidified by coagulation of the albumin. The coagulum, in the first place white, soon becomes yellow from below upwards. When one is dealing with true bile pigment, a blueish ring with greenish reflection appears, either above the yellow portion or at the point of contact of the two liquids.

The color of the serum does not appear of great importance to Borrell, because with Hyem, he admits that the bile pigments, even those which do not give rise to Gmelin's reaction, give to the serum a greenish yellow color, which prevents one from deciding positively the exact nature of the pigment. And what is more, the spectroscopic examination can give no useful data, because the bile pigments, whether normal or modified, produce an obscurity on the right of the spectrum. By the aid of these procedures, Borrell found Gmelin's reaction positive in the serum seven times. In four cases it was negative and as he never found true bile pigment in the urine, he concluded that he was dealing with an acholuric hemapheic icterus, the acholuria being due to a small quantity of bile pigment, this being explained by a certain degree of renal insufficiency.

In the following year (1900), Gilbert and Lereboullet took up the study of acholuric icterus and insisted upon its familial character. In this study they formally concluded that there is a constant presence of the bile pigments in the blood-serum.

The limits of this lecture would be far outreached should I attempt to give a complete résumé of all the work done in reference to icterus, and I shall now pass over the next decade and arrive at the year 1911. At the same time that the notion of hemolytic icterus became more precise researches were also made to explain the causes of hemolysis. It was necessary to discover a cause of hemolytic iterus in which there was no fragility of the red blood-cells. This cause was found to reside in special substances termed hemolins.

I can not go into the history of the complex study of the hemolysins, but for this would refer you to Troisier's thesis and the report read in 1911 at the Congress of Medicine at Lyons, by Guillain and Troisier on the part played by the hemolysins in pathology. Thanks to the study of the hemolysins undertaken at the same epoch, icterus accompanying various affections has now become included in the class of hemolytic icterus, differentiated into several types by Chauffard, Widal, Abrami, and Brûlé. Yet in spite of all this work the study of icterus would have been incomplete if, during the above mentioned researches, one had not endeavored to explain the still old problem of the pathogeneses of icterus, viz., where did the transformation of the pigment resulting from the hemolysis take place; whether or not this transformation could take place without the direct or indirect action of the liver; whether or not, in a word, there existed extrahepatic biligeneses (the so-called local biligenisis) and if they could give rise to generalized jaundice?

Let me say that the cases so far reported to solve this problem are numerous.

I shall have finished with the history of the problem of the pathogenesis of icterus when I shall have mentioned that Chauffard, Laroche and Grigant (1911), Oulmont and Boidin (1912), and P. Mauriac (1912) noticed that in icterus from retention where the globular resistance was increased, the quantity of cholesterin was also; that on the other hand, in cases of hemolytic icterus where there was globular fragility, there was also an hypocholesterinemia, seeming to indicate that there is a relationship existing between the globular resistance and the quantity of cholesterin, and from this very fact the study of the latter should find its place in that of icterus.

3 Rue Bellot.

SOME CLINICAL FEATURES OF EXOPHTHALMIC GOITER.*

By C. V. R. BUMSTED, Ph.B., M.D.,

NEWARK, N. J.

ASSISTANT ATTENDING PHYSICIAN TO THE GERMAN AND ST. MICHAEL'S HOSPITALS; PHYSICIAN TO THE MEDICAL CLINIC OF ST. BARNABAS AND THE BABIES' HOSPITALS

PROBABLY in the whole domain of medicine there is no disease or morbid condition which in the past few years has been the subject of such careful study, investigation, and research, and which is of such interest to both surgeon and internist, and yet presents so many problems for the activities of the various specialties, as exophthalmic goiter. In inviting your attention to a consideration of some of its many features, we do so, fully realizing, in a brief paper of this character, the folly of attempting more than to emphasize the importance of some of its diagnostic facts and clinical relationships. There can be no pretense of presenting the Morbus Basedowii in its entirety and it is with regret that we appreciate that necessity compels the curtailing, in our discussion, of many interesting points, the ignoring of important facts, and the limiting of the scope of such a vital comprehensive subject. The inadequacy is unavoidable.

If we are to appreciate the symptom complex of this disease it is essential that we briefly consider its pathology and especially the pathological physiology. The pathology is by no means constant, its changes being variable and manifold. "These changes are not constant, since the exophthalmic goiter syndrome, as at present recognized, may coexist with a normal thyroid, with a colloid goiter, with an actively hyperplastic thyroid, with an atrophic thyroid, or with a tumor of the thyroid." (Marine.) It is with this broad comprehensive idea and view of the condition that the clinician must base his diagnosis and treatment.

The anatomical changes of true exophthalmic goiter may be roughly divided into two classes: (1) Proliferation or active thyroid hyperplasia with hypersecretion. (2) Degeneration, with possibly hyposecretion.

At first there is hyperemia and we have an increase of the alveolar cells with, in many cases, reduplication of the cellular layers or even papillary formation. The number of the alveoli may be increased. Wilson has shown that in a thyroid analysis of 284 cases prior to 1908, 76 per cent. showed primary parenchymatous hypertrophy and hyperplasia, and in 1911 and 1912, with more careful study and minute investigation, all the cases, 431, coming to operation in the Mayo clinic showed similar pathological conditions. Besides the hyperplasia, the alveoli contain a considerable amount of a thin colloid secretion. The gland is enlarged in nearly all cases, although this is not always discernable in situ by palpation. Kocher found this true in 800 cases, so now the assumption that Graves' disease occurs without enlargement of the gland should be given up.

The degenerative changes may rapidly occur or develop slowly, with lessening or even considerable remission of symptoms. The alveolar epithelium shows exfoliation and necrosis, with even, in some instances, complete destruction of the parenchyma. The colloid material, if present, is dense and stains deeply. Thompson has shown that when the degenerative process is well marked with the secreting cells destroyed, the symptoms of exophthalmic goiter may persist as a result of the previous intoxication and that the surgical removal of such a gland is unnecessary.

The internist must recognize the pathological changes in another group—that of toxic non-exophthalmic cases. They consist, according to Plummer, of about 28 per cent. of all goiters reported as non-hyperplastic. Plummer divides these intoxications into two groups: "(1) A group in which the cardiac toxin predominates and in which the clinical picture closely resembles, and, in many instances, cannot be differentiated from the cardiovascular complex resulting from alcoholic, leuetic, septic, and other well known toxins; (2) a group more closely presenting the picture of Graves' disease and including the cases that have been erroneously so diagnosed by the mass of the profession." Wilson, in 374 cases, has investigated the pathological picture present in these groups and states "that one-half of the thyroids from the toxic non-exophthalmic cases which more or less resemble true exophthalmic goiter (clinical group 2) are of the regenerative type and nearly all the remainder are fetal adenomas, while, in contrast to this, only one-eighth of the thyroids from the toxic non-exophthalmic cases which do not resemble true exophthalmics (clinical group 1) are of the regenerative type, less than one-fourth are fetal adenomas and more than three-fifths of them are adenomas or colloid adenomatoses, with adult and atrophying parenchyma."

The pathogenesis of this disease and its manifestations has not yet been definitely and positively proved. However, facts are slowly accumulating that a thyroid secretion circulating in the blood is the direct cause of all the toxic symptoms. This has been experimentally shown by Edmunds, Baruchi, and French, who were able to produce the symptoms of exophthalmic goiter in lower animals by injecting extracts of ordinary human goiters, and some observers have recently claimed to have demonstrated the presence of the actual gland secretion in the blood. Besides, the effect of overdosing with thyroid extract or iodine by producing symptome of hyperthyroidism would clinically substantiate the above contention. Walton quotes the work of Wilson and MacCarty, who found that the amount of hyperthyroidism runs parallel to the extent of cellular proliferation, which is the histological picture expected to be present from glandular hyperactivity. Klose and Carlson believe that the condition present in exophthalmic goiter is not due to an excess, but to alteration of the normal thyroid secretion. It is interesting to note, however, that Marine and Lenhart have come to the conclusion that the thyroid involvement is not the cause of the disease, but only part of its general picture.

It is possible that other ductless glands are at fault and their internal secretions, either in excess or pathologically altered may be factors in the production of the thyroid hyperactivity. The thymus, especially, is held by many to be responsible. Thorbecke, Boit, Monkeberg, Van Hansemann, and Melchior have all called attention to hypertrophy of the thymus and its persistence in Graves' disease. Berry states that enlargement of this gland has been noticed in every post mortem that he has made, and Matti found a hypertrophied thymus in 75 per cent. of 133 necropsies, while Capelle and Bayer have found the same condition in 43 out of 60 autopsies (70 per cent.). This hypertrophy may

*Read at the meeting of the Newark Medical and Surgical Society, December 17, 1914.

be due to a vicarious endeavor on part of the gland to supplement or supplant the activities of the diseased thyroid, or it may be the sign of a status thymicolymphaticus. Its removal has been advised by Garre and condemned by Gierke, who believes that its definite enlargement is a contraindication for thyroidectomy, which if done produces a thymogenic auto intoxication. Its relationship to exophthalmic goiter is unquestionably close and vital, but at present we are in the dark as to its value. The same may be said of the parathyroids, the pituitary and the adrenal glands, whose internal secretions undoubtedly have a relationship and interaction, as yet unknown, with the normal function of the thyroid gland and which, if either pathologically altered or in excess, have an important bearing on the gland's activity, and possibly on the genesis of a diseased condition.

The role of the nervous system in the production of this disease either by actual lesions in the restiform bodies, or physiopathological derangements in the sympathetic or central nervous systems, or by imperfect functionating of neurogenous tissue, has now but few supporters. Crile, however, has advanced an ingenious theory which, etiologically, apparently has many clinical facts to sustain it. According to Frazier, "He concludes that in exophthalmic goiter a pathological reciprocal interaction between the brain and the thyroid glands exists, and that this reciprocal interaction can be maintained through a nerve connection only, or possibly by a hormone action."

We shall make no attempt to discuss fully the etiology of Graves' disease; there are, however, two classes of cases which are often overlooked and which it is important to recognize: those showing the influence of heredity, and those developing after acute infections. The need of securing a history of the occurrence of cases in the same family or in successive generations is often neglected. Such a familial record is not as uncommon as has been supposed, and careful inquiry will often bring out the fact that symptoms suggestive of thyrotoxic conditions have existed in other members of the family, or even an actual occurrence of a true exophthalmic goiter. There have been reported many such cases, for instance: Rosenberg reports a series in which grandmother, father, two aunts, and two sisters were all affected and you will recall Oesterreicher's classical family of which 8 out of 10 children were exophthalmics. For the past five years the writer has attended a family of four sisters in which the two older sisters had the disease in a severe form and the youngest, a girl of 16, showed symptoms of a beginning intoxication; the other sister, a girl of 20, was free from symptoms while away at school, but when living with her sisters during the summer, developed toxic symptoms. It is important to remember this class of cases, especially when there is a family taint of chorea, epilepsy, hysteria, or insanity, so that when a case develops, slight symptoms in other members of the family may be looked for and appropriately treated.

The importance of recognizing that the malady is often consequent upon acute disease is not sufficiently appreciated. Careful inquiry will often elicit the fact that "colds," tonsilitis, quinsy, or many of the acute infections preceded the symptoms. "DeQuevain has found a subacute thyroiditis quite common in these conditions, especially influenza, typhoid fever, rheumatism (as Parry's first case), and diphtheria, and this thyroiditis was followed by Basedow's disease within a few months in about 20 per cent. of the cases." (Hirschfelder.) Influenza especially seems to be a causative factor; in a series of 86 cases, A. Kocher and Landstrom found it in 7 instances. The following case, seen a few years ago, will illustrate its occurrence. A woman of 32, who had a simple enlargement of the right thyroid lobe, convalescing from a severe influenzal infection, which had been febrile for about 10 days, insisted on attending to her household work. The first day up from bed she collapsed and the next day was found to have unmistakable symptoms of hyperthyroidism. These persisted and in a few weeks she presented all the cardinal signs of Basedow's disease. Medical treatment was unsatisfactory as the patient would not cooperate, so thyroidectomy was done, a year later, at the Royal Victoria Hospital, Montreal.

It is well known that the bacillus typhosus is often a causative agent. Boggs and Sladen have found mild thyroiditis present in most cases of typhoid fever in which the pulse is over 120 at the height of the disease. The writer has seen sudden acute thyroiditis with symptoms of severe hyperactivity develop in the course of a fatal case of typhoid in a goitrous woman when told of the death of her only child. The following case report is interesting on account of the development of exophthalmic goiter during convalescence from typhoid as well as the age and sex of the patient.

Case I.—The patient was a man, 54 years old, whose personal and family history was negative. He was taken ill the latter part of April, 1911, and although feverish and feeling debilitated, attended to his work for two weeks before consulting a physician. It was found that he was suffering from typhoid fever and he went to bed on May 6th, remaining there 31 days. His typhoid was a mild one and he had no untoward symptoms or complications until he got up. His convalescence was progressing favorably until June 15, when thyrotoxic symptoms suddenly developed, he began to complain of sleeplessness, palpitation and pounding of his heart, shortness of breath, and hot flushes. Before his attack of typhoid he weighed 194 pounds and maintained approximately this weight, due to high caloric feeding, during his illness, but now noticed that he was rapidly losing weight. The patient also complained at this time of severe pruritus and it was remarked that in a few weeks his hair had turned from black to a decided white. This patient was seen by the writer on February 6th and the above facts elicited. He was complaining of all the above symptoms and remarked that his disposition had changed completely, as he was now nervous, cranky, morose and unable to concentrate his mind on any subject. He presented a typical picture of Basedow's disease in an advanced stage, his exophthalmos was marked and all the classical signs were present. His weight was 148, pulse 126, systolic blood pressure 152. The thyroid gland was not greatly enlarged, although it was easily palpable, especially the right lobe where a musical systolic bruit was noticed. His heart was enlarged to the left with the apex beat in the fifth interspace, 2 cm. beyond the nipple line. At the apical area there was heard a well marked systolic murmur which was heard all over the heart and transmitted up the vessels of the neck. There was a pronounced systolic shock, the second sound was accentuated. Tremors of the fingers of both hands were very marked, the patient being unable to write at times. Besides the above symptoms, the patient was especially complaining of insomnia, frequent urination and a moderate diarrhea.

The possibility of tuberculosis being the cause of Basedow's disease should be kept in mind. Its association with this disease is not as uncommon as formerly supposed; Bialokur in his cases has found that 27 out of 337 patients with pulmonary tuberculosis presented symptoms of hyperthyroidism. He furthermore states that in his experience

every patient with exophthalmic goiter was already tuberculous. This is probably overestimating the frequency of this combination of diseases, but it is a fact that it may occur, and it has long been known that enlargement of the thyroid may occur in incipient cases of tuberculosis. Primary tuberculous disease has not been observed, the infection occurs from an associated pulmonary lesion, or perhaps more frequently from neighboring lymphatic glands. Early exophthalmic cases may simulate this tuberculous involvement by having, as Stern has shown, an afternoon temperature ranging around 100°. Clinically this thyrotoxic fever is important in differential diagnosis, as a tachycardia with a persistent afternoon temperature of 99.5°-100.5° might easily lead to the error of considering the case a tuberculour one, or on the other hand the presence of an active tuberculosis might be overlooked in a true case of Graves' disease.

If we study the records of our Newark hospitals it would seem that exophthalmic goiter is a rare disease in contrast with its incidence in other cities. In St. Barnabas Hospital, for instance, in the four years, from 1911 to 1914, there were treated in the wards and Out Patients' Department 5,379 medical cases with but 10 cases of exophthalmic goiter, or 0.18 per cent., and in St. Michael's Hospital in the five years, from 1909 to 1913, there were seen 20 cases of exophthalmic goiter out of 14,495 medical cases treated in wards and clinic, with a percentage of 0.1 per cent. While in the Toronto General Hospital during five years, ending December 31, 1909, there were 55 cases out of 8,489 medical admissions or 0.65 per cent., and in the last 4,000 cases in the Montreal General there were 23 cases of exophthalmic goiter or 0.57 per cent. This would indicate that Graves' disease is from three to four times as common in these Canadian cities as in Newark; manifestly the figures from our own hospitals do not give the correct idea as to the frequency of this disease. It certainly is more common in private practice. Probably we are at fault and do not recognize the disease as readily as we should. Undoubtedly there are many of the milder forms which escape us and it is with these early manifestations that so much can be done by appropriate treatment, and the chagrin of vainly treating other conditions for it, be avoided. As Stengel says, "We must recognize that the syndrome may occur in a more or less pronounced degree in transitory and benign affections of the thyroid gland as well as in the more permanent organic conditions that usually occasion it."

It is the writer's belief that there is, in many cases, a decided interrelationship between a persistent hyperemic condition of the thyroid at puberty and the development of Basedow's disease later in life, which as Plummer has shown, generally begins at the age of 32 and occurs in females in 95 per cent. of cases. This condition in adolescence is far more common and important than the profession has recognized. Cross has recently called attention to it. The patient, a girl from 12 to 16, is usually markedly nervous, sleeps poorly, and has developed rapidly. The thyroid is observed to be enlarged, especially the right lobe, and is often tender and occasionally painful. Slight tremor of the fingers may or may not be present. There is generally a slight tachycardia. Cardiovascular and exophthalmic symptoms are not present. There is generally a simple anemia or a chlorosis and it is interesting to note that Handmann reports 44 cases of chlorosis which showed enlargement of the thyroid in more than half the cases. This chlorosis or chloroanemia, in some cases, may be the cause of this condition, although it is probably due to a hyperactivity of the gland influenced by the altering of other internal secretions at the time of puberty. The condition is a pseudo-hyperthyroidism—a simulation of the true disease, and, although transitory, should not be ignored and should have careful attention and treatment. Such a patient should be warned against unhygienic habits, nervous strains, and excitement, and be carefully watched for years, so that the first tendency to the development of exophthalmic symptoms in later life can be noted and the disease treated in its incipiency. The following will illustrate this class of cases:

Case II.—The patient, a well developed girl of 14, complained of nervousness, inability to study, poor appetite, and sleeplessness. Her pulse was 128, and the thyroid gland was painful at times, tender on pressure and symmetrically enlarged. Her hemoglobin was 60 per cent. The hygiene of her life was regulated, simple medical treatment instituted and the patient kept under observation for 18 months. When seen last week, four years after the developing of the above symptoms, the thyroid was only a little full, her pulse rate was 80, and she had none of her previous symptoms.

Case III.—A thin, nervous, sallow looking young lady of 29. She complained of poor appetite, constipation, insomnia, and irritability. Her thyroid was not enlarged, but she had a pulse rate of 142 and there was a marked tremor of the fingers of the left hand. Her weight was 92 pounds, and her blood showed a slight evidence of chloroanemia. There were no cardio-vascular or ophthalmic signs except possibly a slight prominence of her eyeballs, which may have been normal. The patient stated that as a girl, from 14 to 17, she was very nervous, anemic, and out of school most of the time. She complained of a swollen neck for several years and remembered that it was painful and tender because she could not wear a tight collar.

Undoubtedly many cases escape us and are treated for hysteria, nervousness, neurasthenia, insomnia, or else are ignored entirely, merely because we expect to find the complete symptom complex in every case and refuse to recognize that the transitory and atypical and aberrant forms are the most common. As the pathological picture varies, which we have seen occur, the clinical aspects change, There need be no constant sign. Exophthalmia is rarely seen early and the four classical eye signs may never be observed. The thyroid may never show palpable enlargement. Glycosuria may be the only important feature. The circulatory phenomena vary with the intensity of the hyperthyroidism. Neurasthenia, insomnia, rapid loss of weight, excessive sweating, diarrhea, muscular weakness, and disturbances in the general health all call for investigating the activity of the thyroid gland, and it will be surprising to find how many cases of Graves' disease are manifesting some one or more of these symptoms. "The more one studies hyperthyroidism," writes Stengel, abstracting an excellent paper by Lambert, "the more one realizes that it is an expression of the algebraic sum of many morbid processes—some of these arising in the thyroid gland, others in the parathyroids, others in the pancreas and adrenals, or in the general metabolism of the liver itself; and there are evidences that the pituitary body and the ovarian secretion are not unimportant in the interrelationship among these many glands, and not without their influence in the varying expressions of the general metabolism of the body. Hyperthyroidism is not an entity, it is not the expression of a single influence. It is the manifestation of a lack of equilibrium in the rela-

tionship of many glands in the body, and this equilibrium may be upset by an increased function or a lack of function of any one of these related ductless glands. We must, therefore, realize that when we consider the atypical forms of Graves' disease, the thyroid gland may be the least at fault; and furthermore, we must realize clinically that where tachycardia is present, we should think of some disturbance of internal secretion, and not put it down to mere nervousness, thus dodging the responsibility of a more accurate diagnosis. When nervous irritability and change of disposition occur, when formerly reasonable patients present a veritable chorea of intellectual functions, we should not attribute it to neurasthenia, but realize that they are suffering from internal poisoning, which we have been accustomed to consider as part of the symptoms of Grave's disease, and which we would readily recognize if the full picture were present, with exophthalmus, goiter, and the tachycardia combined. As long as the goiter or the exophthalmus is present, or the tremor with the tachycardia, there is no question that the patient will be quickly placed in the proper clinical group; but it is in those cases in which the symptoms which we formerly considered to be cardinal are absent, or where they are present only in a slight degree, that we usually fail to recognize the chief disturbance as one of upset equilibrium among the ductless glands."

The clinical manifestation of the thyrotoxicated heart are the most interesting, and with tachycardia the most important symptom of this disease. The cardiovascular disturbances occur very early. They are never absent and may exist for months before other evidences of the disease appear.

(1) The earliest complaint is of palpitation, the pulse rate is rapid and feeble, often as high as 150 or more, but tachycardia often exists without the patient being aware of it, and in a few instances the pulse rate is normal. Arrhythmia is rare.

(2) Cases frequently show paroxsymal dyspnea.

(3) The heart is often felt to be "pounding" with or without a systolic thrill or diastolic shock. The apex beat may not be much displaced outwards, although dullness is generally increased to the left. Murmurs are common especially at the apex. There may be a diastolic murmur at the aortic area. The cardiac muscle is dilated in about two-thirds of the cases with a consequent systolic murmur, heard best over the second left costal cartilage and sometimes propagated up the vessels of the neck.

(4) The vascular changes are striking. The carotids alone may be involved. The retinal arteries and the abdominal aorta often pulsate so violently as to be very annoying to the patient. Capillary and even venous pulse may be found. "Very frequently on auscultation over the arteries a sound like Traube's sound in aortic regurgitation is heard and sometimes a double murmur. Venous hums in the neck are exceedingly common and the bruit often described as occurring in the enlarged thyroid is generally produced in the dilated veins lying at the sides of the gland or elsewhere adjacent to the goiter. A bruit in the gland itself is probably quite rare." (Stengel.) The systolic blood pressure may be low or normal, but it is more often high.

It is an erroneous impression that exophthalmic goiter is practically incurable. It is true that poor results are often obtained, but they are usually due to a lack of knowledge of the pathology of this disease and its pathological physiology, together with an inadequate idea of the precise indications for the use of definite therapeutic measures. There is no specific treatment. Individualization is the keynote. Surgery is applicable to many cases, although we believe medical measures are more appropriate for the larger number. There are apparently many roads to Rome. It is indeed unfortunate that there is such diversity of opinions as to treatment, all tending to confuse the practitioner as to the best methods to follow in a given case.

Before beginning treatment it must clearly be kept in mind that the clinical manifestations are due to hypersecretion of iodized thyreoglobulin and that this is in proportion to the blood flow through the gland. As Hirschfelder clearly states, "The first essential of any palliative treatment, therefore, is to reduce the thyroid secretion to its lower ebb by the removal to the two stimulating causes, exercise and excitement. In the mild cases a simple isolation cure, with absolute rest in the horizontal position, can sometimes so lessen the flow through the thyroid and the secretion of this gland by diminishing the size and number of heart-beats that the thyreoglobulin content of the blood falls to normal and symptoms subside. If the rest cure be prolonged, the slight glandular hyperplasia of early cases may subside and a permanent cure may result." This rest will usually quickly cause the palpitation and tachycardia to subside; if it does not the intermittent application of a light ice bag to the precordia is advised. The importance of rest cannot be overestimated.

Cardiac stimulants should be used only when there are definite indications of cardiac weakness and where the cardiac symptoms predominate the case. Digitalis is the best, with strophanthus for use in milder cases. I can see no indication for strychnine or camphor except in terminal conditions. Belladonna and atropine, although advised by some, apparently have no effect except in cases showing loss of vasomotor tone; the same may be said of ergotin.

Cases will have to be individualized. Those with nervous disturbances should always be put on some of the milder sedatives, as bromide. Veronal and trional and the other soporifics are useful when indicated. Hydrotherapy is useful in these cases, especially during the first few weeks of the rest cure. Lukewarm baths, warm salt baths, spinal douching, cold packs before retiring, and ice frequently applied to the gland itself are very helpful in most cases where the nervous symptoms are present.

Muller, Jackson, Solis-Cohen, and Forschheimer have warmly recommended the use of quinine, especially the neutral hydrobromate given in 5 grain doses three or four times a day. This, in my opinion, is of decided value in more than half the cases. Cinchonism is seldom produced and the drug can be taken for months with no deleterious effects. It, with other simple therapeutic measures, has cured several of my cases which have resisted all treatment, including operative. To quote Forschheimer's own words, "The good effects under this treatment usually follow in the same sequence; first, the tachycardia improves, the pulse frequently coming down from 130-140, pulse beats to 80 or 90 in forty-eight hours. Secondly, the thyroid gland diminishes in size, by measurement. Thirdly, the tremor and exophthalmus is the last symptom which disappears; indeed, in a goodly number of patients it never disappears. To convince oneself that the treatment is the cause of the changes just noted, it is necessary

only to withdraw the pills and, unless the patient is cured, the symptoms recur. If after the withdrawal of the pills the symptoms disappear, such patients, as a rule, may be considered cured. Relapses are not uncommon; these patients have relapses on account of psychic or physical irritations, and these relapses should be treated in the same way as before. It is on account of these relapses that the disease may last so long. The treatment just described is most valuable in the mild attacks, the percentage of complete recoveries being very large, and after a short time. When the fully developed form exists, either primarily or as a relapse, complete recoveries are the rule, but more time is required. When the patient has the foudroyant form the results are excellent, so much so that if one believes only in surgical treatment the quinine and ergotin may be given to get the patient in condition for the operation, as has already been done by Deaver." The ergotin, which Forschheimer and Solis-Cohen recommended to be given with it did not seem to have any appreciable influence.

In cases which do not respond to the quinine therapy calcium salts, especially calcium lactate, should be used. Blair Bell has shown that the thyroid secretion exerts a powerful influence on calcium metabolism. Sir James Barr, who has had an extended experience in this disease writes, "I now think that the soluble salts of calcium, especially when combined with adrenalin, constitute our best remedy in this disease. The suprarenal and pituitary secretions help to retain the lime salts in the tissues, but the pituitary should only be used when the blood pressure is low, and there is reason to believe that the suprarenal glands are inactive."

The patient should be placed upon as liberal a diet as can be assimilated. Most cases have lost considerable weight. A régime similar to the one adapted to the treatment of pulmonary tuberculosis is often indicated. While the diet is not generally an important factor in the treatment, it should consist chiefly of milk, green vegetables, farinaceous foods with plenty of fat, and a minimum of red meat. Sodium chloride should be freely used in the diet. It is well to avoid acid fruits, and remembering that a comparatively large percentage of cases show a carbohydrate intolerance as manifested by a slight glycosuria, the sugars should be carefully given and in some cases eliminated entirely from the dietary.

The indication for iodine, preferably Lugol's solution, is most important to determine. The use of iodine is dangerous in most cases, but in others it apparently has a curative action. Other methods should be used first and then, if possible, the case studied with the attempt made to determine if the gland is undergoing degenerative changes, for then only can iodine be safely used. The investigations of Baumann, Ross, and Oswald have shown the active principle of the thyroid gland is a globulin which is first formed within the cells containing no iodine and is physiologically inactive until it acquires its iodine from the blood and is iodized, becoming iodothyreoglobulin. When there is an excess of iodine in the blood content the thyroid cells are stimulated to hyperplasia and the amount of iodothyreoglobulin is increased, giving the physiopathological basis for exophthalmic goiter. When the blood content is low in iodine the thyreoglobulin is not iodized and accumulates in the cells, which are saturated with iodine-free thyreoglobulin and colloid degeneration ensues, thus producing the pathological picture of simple colloid goiter. It can be readily seen that iodine should only be given in the non-hyperplastic types of cases and in those patients who show clinical evidences that the thyroid is undergoing degenerative changes. It does harm by activating the thyreoglobulin and may bring on an accerbation of the disease. A case illustrating this effect was recently seen in St. Barnabas Hospital. The patient was a goitrous woman (M. W. 28,619), 48 years old, who presented the symptoms of a moderate degree of hyperthyroidism. After an attack of measles, when she was 16 years old, the thyroid gland slowly began to enlarge and showed symptoms of hyperfunctionating. The enlargement of the gland reached its maximum when the patient reached the age of 25. This condition, with very slight symptoms of hyperactivity, existed until 10 months ago when the patient was placed upon iodine and chromium sulphate with unguentum iodi rubbed into the gland. As the result of this treatment, the patient rapidly began to develop marked symptoms of hyperthyroidism and when seen by the writer, presented nearly all the classical signs of exophthalmic goiter.

We have had no experience with galvanization, *x*-rays, thymus, or parathyroid extracts, rodagen, a powder made of the dried milk of a goat whose thyroid has been removed, or the specific sera of Mobius or of Beebe. Favorable results have been reported by some observers, especially in the use of Beebe's serum, but further confirmation is needed. It is the general opinion that of all the glandular extracts that have been used thymus extract has given the best and most permanent results, and its effect is greatly increased by giving with it small doses of adrenalin.

The results of cases medically treated are not sufficiently appreciated by the profession. A careful study of the results obtained by many men, Hale White, Mackenzie, Musser, and others sustain Solis-Cohen's contention that "under medical management one may reasonably hope for the recovery of not less than 75 per cent. of patients exhibiting Grave's syndrome." These results are about the same that are claimed for surgical treatment in the hands of competent men, as McWilliams has shown in his review of the results obtained in 514 cases reported by Mayo, Klemn, Riedel, Kocher, and Krecke; of these 72 per cent. were cured, 15 per cent. were improved, 11 per cent. slightly improved, and 3 per cent. were unimproved.

Unquestionably there are many cases which demand surgical intervention and this question must be decided upon on the circumstances and merit of the individual case. Fortunately the operative mortality in good surgical hands is less than 5 per cent., and in men of large experience, as Mayo, Dunhill, and others, who are devoting special attention to these cases, it is less than 1 per cent. or even half of 1 per cent. It must be remembered, however, that recovery from the surgical operation does not necessarily mean recovery from the disease, as any surgeon or clinician will attest. It is most important to decide when a case should be referred to our surgical colleagues, and we think the following conclusions may be safely drawn:

(1) All cases should receive good medical treatment for from three to six months before considering operative treatment.

(2) Surgery should be advised, "when the disease is progressive or far advanced and is either disabling or dangerous, or threatens to become so, even though no sufficient attempt has been made at medi-

cal and hygienic management including rest" (Cohen), and

(3) In cases that cannot take sufficient rest and will not cooperate fully in the medical management of the case.

(4) A patient who is to be operated upon should have at least two weeks absolute rest before being surgically treated.

(5) Cases should be referred only to surgeons who have had large and special training in the operative treatment of this disease, no matter how expert they may be in other fields.

(6) The hyperemic condition of pseudo-Graves' disease in young girls should never be operated upon, as has been the writer's sad experience to see.

(7) Surgical intervention should not be advised in cases of goiter associated with functional or organic disturbances of other secretory organs until the associated disorders are removed or relieved. (Musser.)

(8) After surgical intervention a case should receive appropriate treatment and be under medical supervision, if the operative results are to be permanent.

THE INTRASPINAL TREATMENT OF SYPHILIS OF THE CENTRAL NERVOUS SYSTEM.*

By MARTIN J. SYNNOTT, A.M., M.D.,
MONTCLAIR, N. J.

THE work of Swift and Ellis in treating tabes and syphilis of the central nervous system with intraspinal injections of salvarsanized serum has interested me very much, and I have myself employed this method on several cases. I believe their methods are rational and scientific. Subsequent observations may lead to radical modifications of the technique, but this will in no way detract from them and the other pioneer investigators who have blazed the way in this very important work.

The serological findings in cases of tabes have led me to give the subject considerable thought. In most of the cases I have seen, the Wassermann reaction in the blood has been negative, while in the spinal fluid it has been strongly positive, together with an increased number of cells, up to 40, 50, 60, or higher, and an excess of globulin.

In cases like these, where the blood is negative to the Wassermann, but the spinal fluid positive, it has occurred to me that simply draining off the spinal fluid might do much good. In these cases the blood may be rich in spirocheticides, whereas the contents of the infected spinal cavity may be very low—in fact the immunizing substances necessary to combat the spirochete may be exhausted.

Those of us who are vaccine therapists know that in bacterial diseases we meet not infrequently cases of infections in the body cavities, such as the peritoneum, pleura or an ordinary abscess, where the contents of such a cavity are found to be low in opsonins and other protective substances, while the by-circulating blood contains an excess. We also know that results can be obtained from vaccine therapy only where an efficient lymph stream can be conducted through the focus of infection, and that unless the blood stream with its antibacterial substances has free access to the infected area, an increased opsonic index in the blood does not cure the disease. When such a cavity is drained, however, this procedure is followed by the introduction of fresh fluids from the blood, containing an excess of protective substances, and the cavity is quickly healed.

Thus is explained why cases of tuberculous peritonitis recover without any other treatment than the opening and draining of the peritoneal cavity.

We quite recently have read a report of a cure of a case of tuberculous meningitis in a child where the diagnosis was unmistakably confirmed by the laboratory findings. Here the only treatment employed was daily spinal puncture and the draining off of 10 to 15 c.c. of fluid.

In exactly the same way it seems to me that drainage of the spinal canal in cases of tabes, particularly in those where the blood shows a negative Wassermann might do good. The lymphagogue action following this procedure should bring about the introduction into the infected canal, where perhaps the protective substances have been exhausted, of fresh fluids from the blood, rich in spirocheticidal properties, and this in itself should tend to effect a cure. I offer this

*Opening Remarks of the Discusion of a Paper on the "Intraspinal Treatment of Syphilis of the Central Nervous System," delivered at a meeting of the Orange Mountain Medical Society, November 20, 1914.

merely as a suggestion. It has the advantage over the Swift and Ellis technique in that the danger to the patient is minimized, and the treatment much simplified.

Now as to whether we should use an autogenous or exogenous blood serum, it is my belief that in cases where the patient's blood is negative to the Wassermann, we should use an autogenous serum, because it seems reasonable to suppose in such cases that the patient has won in his fight against syphilis so far as his blood is concerned and that therefore his blood should be high in spirocheticidal substances, whatever these may eventually be shown to be. The introduction of such a serum in appreciable quantity ought to be a valuable therapeutic agent, in the infected spinal cavity, even without the addition of salvarsan. This explains to me why cases treated by the original Swift-Ellis method showed improvement, although by this method the amount of salvarsan in the injected fluid was so small as to be almost negligible.

On the other hand, if the patient's blood gives a positive reaction to the Wassermann test, it seems to me reasonable to assume that it is low in spirocheticidal substances, and that an exogenous serum obtained from human blood known to be healthy is much to be preferred.

THE CLINICAL SIGNIFICANCE OF BLOOD PRESSURE.*

By PERCIVAL NICHOLSON, M.D.

ARDMORE, PENNA.

As a consequence of the ease of blood pressure determination by the auscultation method and its wide advocacy by a number of the leading authorities on medicine, thousands of observations have been taken by general practitioners and specialists and a very large and voluminous literature has rapidly accumulated.

As was only reasonable to expect, a large majority of observers magnified a symptom into a disease and not understanding the physiological and pathological conditions involved in blood pressure observations, in many instances caused considerable injury to their patients by treatment based on a wrong diagnosis. A perfect mania was developed for the reduction of what to many observers were cases of hypertension. This idea of the reduction of high blood pressure has become, I am sorry to say, so prevalent that but a short time ago a noted clinician remarked to me that he thought that the attention called to blood pressure observations had done more harm than good, owing to the effort of the general practitioner to effect a lowering of the hypertension immediately by such drugs as the nitrites.

At present there is a partial reaction and I trust it is only a question of time until the proper interpretation and management of blood pressure cases are more clearly understood and the remarkable practical value of careful blood pressure observations as a means of diagnosis and a guide to treatment appreciated.

In order to understand clearly the significance of blood pressure it might be well to review briefly a few well known facts.

Blood pressure depends on four main factors: (1) the contracting force and rate of the heart beat; (2) the degree of elasticity and lumen of the vascular wall; (3) the volume of the blood; (4) the peripheral resistance. The vasomotor system regulates the rate and force of the cardiac beat in relation to the tone and lumen of the arterioles and capillaries acting as the governor of an engine. The maximum contracting force of the heart is represented by the highest pressure present, systolic or maximal, and the pressure present during the rest period of the cardiac cycle by the diastolic of minimal pressure. The diastolic pressure indicates the amount of peripheral resistance the heart must overcome in order that the various organs may obtain their proper supply of blood.

The pulse pressure, or difference between the systolic and diastolic readings, shows the excess pressure the heart is exerting or the head of flow of the blood column.

The normal systolic blood pressure lies between 110 and 150 mm., varying somewhat according to the age of the patient. The diastolic pressure is between 60 and 105 mm. in healthy individuals.

The range of the pulse pressure given by Barach and Marks[1] is 20 to 70 mm. but Warfield[2] in his latest article found the pulse pressure to be from 30 to 50 mm. Hg. and gives the average between 40 and 50 mm. Hg. The percentage relation of the pulse pressure to the diastolic pressure Barach and Marks give as from 20 to 80 in health.

So that a conservative statement would be that the pulse pressure should not fall below 20 per cent. of the diastolic pressure, with very few exceptions, if a normal circulatory balance is present; anything below shows a pathological condition. The statement of Stone[3] that the pulse pressure should be 50 per cent. of the diastolic pressure under normal conditions has been disproved by Barach and Marks and by Warfield.

From the above it becomes evident that when blood pressure readings are taken by the auscultation method any sustained systolic pressure of 150 mm. Hg. or over would indicate hypertension, or any sustained diastolic pressure of 105 mm. Hg. or over would indicate the same condition. Even if the systolic pressure were below 150 mm. Hg., a diastolic pressure above 105 mm. Hg. would be a sure indication of hypertension regardless of the age of the patient.

On the other hand any sustained systolic pressure of less than 110 mm. Hg. or diastolic pressure below 60 mm. Hg. shows hypotension.

At the outset I wish to emphasize the fact that blood pressure observations should not consist of systolic pressures alone, such readings tell less than half the true situation. It is essential to determine the diastolic pressure (peripheral resistance) and by subtracting the diastolic reading from the systolic obtain the pulse pressure, or head of flow. I wish you to understand clearly as I have expressed in a previous paper,[4] the importance of a complete blood pressure picture. The whole significance of blood pressure depends on the taking of systolic, diastolic, and pulse pressures. The importance of diastolic pressure in this relation is clearly expressed by Barach and Marks[1] as follows: "As time goes on and our observations accumulate and are being interpreted we believe that more and more importance will be attached to the height of the minimal pressure (diastolic) and that the height of the maximal (systolic) pressure will be considered of lesser clinical importance than heretofore. Certainly the maximal (systolic) pressure alone is of no value except as a starting point for a guess as to the activity of the circulatory system."

*Read before the Medical Society of the Woman's Hospital of Philadelphia, December 21, 1914.

Warfield also makes a similar statement:[2] "Moreover, the conviction is growing that it is the height of the diastolic (minimal) pressure rather than that of the systolic pressure that is the really vital point in blood pressure determinations."

A large number of observers have considered the subject of blood pressure in the light of hypertension. It is essential to obtain a full rounded view of the subject of blood pressure if it is to become a practical and dependable aid to the clinician. This can only be accomplished when the systolic, diastolic, and pulse pressures are determined not only in relation to hypertension but also to hypotension and normal readings.

A few days ago I was told: "I think the medical profession has run off on a blood pressure tangent; it is the latest fad in medicine. I do not think that blood pressure observations have much practical significance for the general practitioner." With the above statement in mind and with the time at my disposal I shall try to show you some of the ways that clinical blood pressure observations have a valuable significance in the practice of medicine.

We will consider cases of hypertension as they are the more frequently met. By hypertension I mean any case in which there is either too high a systolic or diastolic pressure.

As a result of a routine examination a patient presenting him or herself to the clinician may be found to have a high blood pressure. There are many such cases of hypertension who come for relief from some slight or marked symptoms which they in no way associate with high blood pressure, or it is found that an applicant for life insurance has an unsupected high pressure. Immediately the question arises in both the patient's and physician's mind what is the significance of the hypertension.

The significance of the hypertension can only be determined by discovering the cause and extent of the condition producing the elevation of blood pressure. This means the obtaining of a thorough and careful history as to vocation, especially as regards occupations in which lead is used; the consumption of alcohol, tea, and coffee; the past diseases, especially typhoid fever, scarlet fever, and other acute infections. Equally important is the character of the food taken, whether mainly nitrogenous or not, and also the amount taken at a time. The amount of elimination by both the bowels and kidneys should be determined. The degree and character of exercise taken and a careful inquiry made as to the nervous tension and strain the patient is living under. The history, of course, is followed by a careful and routine examination.

As by far the largest number of cases of hypertension come from a beginning or established nephritis, especial care should be used to determine whether polyuria and nocturnal uresis are present, and a careful examination of the urine made not only for specific gravity and albumin but also for casts, indican, diacetic acid, and acetone.

Many cases of hypertension are due to focal infections, hence the necessity during the routine examination for especial care in the determination of the presence or absence of sinusitis, chronic tonsillar infection, maxillary abscess, pyorrhea, a chronic cholecystitis, chronic appendicitis, pelvic infections, and intestinal stasis. A careful examination for a blue line on the gums and the red blood cells for basophilic degeneration sometimes will clear up a doubtful case. A Wassermann reaction, especially where sclerosed vessels are present, and an examination of the eye grounds are sometimes of marked service.

By far the largest number of cases of hypertension are due to a toxemia, as yet not determined, though it is thought to be likely an excessive internal secretion from the adrenal or pituitary,[5] but the adrenal as the only source of the hypertension would seem to be disproved by the work of Janeway.[6] Whatever the character of the toxemia, its presence is pretty definitely accepted, and in hypertension the results depend on how readily we can remove it, how long it has been present before discovery, and how much if any permanent damage has been done before it is removed.

It should be clearly understood that not all cases of hypertension are due to toxemia, though the large majority of cases come under this head. There is an increasing number of patients in whom hypertension begins as a result of the high nervous and physical tension under which they are living.

While hypertension is only a symptom and not a disease, a maintained high blood pressure, no matter from what cause, will eventually produce permanent cardiac hypertrophy and vascular sclerosis with degenerative changes in the kidneys. So it at once becomes apparent that in all cases of hypertension an elimination of excessive physical and mental strain is essential if we wish to benefit our patients.

In early cases the discovery of hypertension and its proper treatment means the practical application of preventive medicine.

To determine the clinical significance of hypertension in a given case, after having determined as far as possible the exciting cause, it is necessary to see how the blood pressure and symptoms are affected by certain simple lines of treatment. Remove any focal infections where possible, place the patient on a simple low protein diet, not purely vegetable, but discontinue tea, coffee, and alcohol, and especially limit the amount of food taken at any one time. See that a moderate, not excessive, amount of fluid is taken between meals and keep up elimination by the bowel by means of the simpler cathartics as, cascara, senna, rhubarb. magnesia, etc., with a five-grain dose of blue mass once every week or two. Patients with a large pendulous abdomen should have some form of abdominal support to relieve venous stasis.

Be sure that your patient takes some form of mild exercise, but never to the point of tire. In those in whom the pressure is very high light general massage may be substituted for the exercise. Rest for a short time before and after meals should be insisted on, and when the systolic pressure is 190 mm. Hg. or over at first it is often well to confine the patient to bed, at least for a period of observation. Sweating by hot air or by electric light baths on alternate days, or less often according to the effect produced, while it often does not lower the pressure values, frequently removes uncomfortable symptoms of hypertension. In the well marked nephritic cases treatment of a diuretic nature usually aids markedly. Do not try to lower blood pressure by nitrites and the vasodilators nor by the cardiac depressants, as aconite or veratrum viride.

It is not the lowering of blood pressure that is important. There are however a few exceptions:

(1) In cases where the blood pressure is sufficiently elevated to threaten apoplexy (250 to 300 mm. Hg.) an immediate reduction of blood pressure is indicated, usually by a venesection.

(2) In hypertension with failing compensation

with an overloaded right heart, as in pneumonia, an immediate venesection will often save the patient.

(3) Angina pectoris is also an urgent indication for the use of the vasodilators, as amyl nitrite.

(4) Cases of hypertension in which operative procedures are demanded, where the height of the pressure is such that the giving of an anesthetic is necessary and at the same time dangerous, a preliminary lowering of the blood pressure will often permit of a safe operation.

(5) In patients suffering with cataract and having hypertension, a preliminary bleeding will lower the blood pressure so that a safe enucleation may be performed and the danger of postoperative intraocular hemorrhage avoided.

As a result of simple limitation of diet, elimination, and proper hygiene, as outlined above, some of your hypertensive cases will be free from symptoms and the blood pressure will fall to a normal level. In these patients you have discovered the beginnings of trouble when the hypertension was due to a spasticity of the vascular walls before any sclerotic and degenerative changes had taken place in the blood-vessels and kidneys. The patients are cured and will remain so as long as they are careful to carry out a rational hygiene.

In other cases your treatment, while it may have relieved some or all of the symptoms of which the patient complained, has only partially, if at all, produced any reduction in the blood-pressure figures. Here the hypertension has been present over a longer time, the cardiac muscle is hypertrophied, and the vessel walls are somewhat sclerosed, so that you cannot produce a return of the blood pressure to the normal level even by removing the cause. An attempt at complete reduction of blood pressure would only injure your patient; as a certain increased pressure is necessary to maintain an adequate circulation to the organs, on account of the increased peripheral resistance due to the sclerosed vessels, it is a compensatory condition. All you can hope to do is to eliminate that portion of the hypertension due to increased spasticity of vascular system. A continuance of the simple treatment outlined will prevent further damage, and the patient with care can live a useful and comfortable life, the duration in years depending on the degree of reaction shown to treatment, not necessarily to the numerical height of the blood pressure, though that is very important.

In still other patients where toxemias have lasted over a considerable period, marked and permanent cardiac, nephritic, and vascular changes have resulted so that the treatment given, even though it eliminate the primary cause of the high pressure, will produce no lowering in the blood pressure readings, though it may relieve some or all of the symptoms.

In such cases there is no need to be unduly discouraged. As long as there is a pathologically normal blood pressure maintained with its compensatory wide pulse pressure by hygienic and conservative treatment, such cases may live in comparative comfort for four or five years and in some cases longer. Any fall in the systolic pressure or diminution of the pulse pressure is a bad sign. Many of these cases are improved by small doses of digitalis and tonic treatment.

Even in cases of hypertension which cannot be reduced there was often superimposed attacks of spasticity for which much can be done. The great importance of spasticity in hypertension is clearly shown by the following case:

Male, aged 60 years, seen in consultation two weeks subsequent to an attack of apoplexy; has always been a fairly heavy drinker, mostly of whiskey, and a heavy eater, and takes but little physical exercise; rest of the past history negative. Two weeks before being seen he had an attack of apoplexy with left-sided paralysis, from which he was rapidly recovering until the day before consultation. At this time he complained of severe pain in the region of the umbilicus, and a temperature of 101° F. was noted. On the day seen the temperature was 102° F., all fluid and food were vomited, and the pain in the abdomen was very severe, so that the attending physician had given two hypodermics of one-quarter grain each of morphine. Examination showed a large overnourished man with gray hair, appearing much older than his years. In the general examination the salient points were a moderate left-sided paralysis, a markedly over-action and moderately hypertrophied heart, a general rigidity of the abdomen, and severe cramp-like pain. Pulse was 100, blood pressure 180 mm. Hg. Systolic, and 160 mm. Hg. diastolic. I was informed that the blood pressure had been the same for a week previous. The treatment had been tincture of aconite and veratrum viride in large doses, together with potassium iodide. The urinary secretion for the last twenty-four hours had been only seventeen ounces. All medication was discontinued and salt solution given by the bowel and hot applications placed on the abdomen. In twenty-four hours the urinary output rose to seventy ounces, the temperature fell to 98° F., and the blood pressure readings to 160 mm. Hg. systolic, 110 mm. Hg. diastolic. The blood pressure has since remained around the same level and the patient is entirely free from pain and has recovered the use of his left side almost entirely.

The significance of the symptoms found in hypertensive cases is very exhaustively treated by Janeway,[7] but owing to the time required to discuss them I shall have to omit them here.

Warfield's[8] conclusions in regard to pulse pressures to me are a very valuable aid in determining the significance of blood pressure in the cases we are discussing: "In general when the systolic pressure is normal, increased pulse-pressure signifies peripheral dilitation. When the systolic pressure is high the increased pulse-pressure is to be regarded as normal and has no special significance. Decreased pulse-pressure or even normal pulse-pressure means marked peripheral constriction, and is, therefore, an unfavorable sign. With low systolic pressure increased pulse-pressure occurs in practically only one condition, aortic insufficiency. With normal systolic pressure gradually decreasing pulse-pressure usually means cardiac failure. The condition is seen often in the later stages of the high systolic increased pulse-pressure cases. With low systolic pressure decreased pulse-pressure usually means general cardiac weakness, as seen in febrile conditions or in convalescence from long illnesses or in cachexia or malignant disease."

Lichty,[8] after stating that great care should be exercised in the prognosis, makes the following generalizations:

"(1) Where hypertension exists with but little or no recognizable disturbed function of other organs the outlook is most favorable. (2) Where it is associated with marked disturbance of any one other organ alone it is more serious. (3) Where it is associated with great defect of several other organs, such as kidney insufficiency, cardiac insufficiency, cirrhosis of the liver, and lesions of the gastrointestinal tract, the prognosis is most serious. (4) When the hypertension is associated with symptoms and physical signs which disappear after a more or less active and prolonged treatment which, however, fails to lower the tension, a favorable prog-

nosis is not unwarranted. Such cases are rather frequent, and I believe it is just as unreasonable to take an unfavorable view of them as it is to predict a speedy fatality in all cases of pulmonary tuberculosis where the bacilli are found in the sputum. (5) When the tension is found in connection with changes in organs producing such extreme symptoms as dropsy, ascites, cyanosis, and orthopnea, and when these symptoms cannot be relieved, whether the tension is modified or not modified by heroic treatment covering five to eight weeks, then defeat is sure. And extraordinary measures, such as drastic purging, venesection, and medication with excessive doses, are entirely useless, or effectual only for a short time, and sometimes more cruel than humane."

The significance of blood pressure as regards hypertension in the more acute conditions that arise in obstetrics, cerebral concussions, and fracture of the skull, I shall leave to those discussing surgery, obstetrics, and medicine. The subject of hypotension, normal blood pressure, and blood pressure in children I shall leave for future consideration as time does not permit a discussion of them now.

THE ABORTION OF TYPHOID FEVER.

By WILLIAM LAWRENCE FRAZIER, M.D.,

MOUNTAIN HOME, IDAHO.

MEDICAL DIRECTOR OF THE FRAZIER LABORATORY.

THOUGH it has not been demonstrated by so many authorities or to so great an extent, that typhoid fever can be aborted, as it has been demonstrated that it can be prevented, it has been just as surely demonstrated.

I published an article in the MEDICAL RECORD, November 11, 1911, on the "Use of Ipecac to Abort Typhoid Fever." In this article was given a brief record of several cases of typhoid treated by the use of salol-coated capsules of ipecac. Treated by ipecac in this way, the fever was aborted in from four to six days. But there were some disadvantages in this mode of treatment. If the salol coat became broken before the capsule left the stomach it caused vomiting, or if the salol coat was too thick it passed through the entire alimentary tract undissolved. These factors made regulation of dosage difficult. The method of treatment has been modified to overcome these difficulties. Instead of ipecac, the active principle is given hypodermically in the form of emetine hydrochloride. By administering it hypodermically the probability of producing vomiting is done away with, the dosage can be accurately regulated, it can be given to children who could not swallow a capsule, and instead of taking from four to six days to abort the fever the results have been an abortion in from two to four days. In only six cases of a series of eighty-two treated by hypodermic injection of emetine hydrochloride did the fever run longer than four days after the treatment was begun, and none of these six extended over a period of more than six days.

Three of these cases were first seen about the beginning of the third week, and very small doses were given. The other three were given a preparation which on test proved to be very low in active principle, and was discarded and a tested product used. Because of this we have established a laboratory for the purpose of being able to test our product. It would be as disappointing to try to abort a case of typhoid fever by using a poor qualilty of emetine, as it would be to try to cure a case of diphtheria with a serum from an animal which had not been properly treated.

Emetine hydrochloride may be called a typhoid fever abortant and discussed as follows:

Animal Tests.—The injection of large amounts into guinea-pigs, cats, dogs, and goats, without producing toxic symptoms proves the preparation harmless. Six times the ordinary dose has been given man without producing toxic symptoms.

Culture Media Tests.—The serum from the blood of the goat taken twelve hours after the last of the sereis of three injections of one-half grain to each injection, will not serve as a medium upon which to grow typhoid bacilli; and a colony planted on it dies within ten hours.

Bouillon, agar, and serum media in one to twenty-five thousand mixture will not support the growth of typhoid bacilli; and colonies transplanted on to these media quickly perish.

Indications Relative to Typhoid.—It is indicated in typhoid fever as an abortant, and in those exposed to typhoid as prophylactic. As an abortant it should be used as early in the disease as possible. In epidemics and cases known to have been exposed it should be used as soon as any symptoms of typhoid appear. Its being nontoxic renders early use justifiable. It is impossible to emphasize too strongly the necessity of early usage. As a prophylactic it is of benefit only while in the circulation, and for this reason should be given every twenty-four hours. It is recommended as a prophylactic to be used only until immunity can be established by the ordinary prophylactic.

Dosage.—One-half grain is the adult dose. For individuals over fifteen the adult dose is suitable unless the individual is underweight; in children twelve to fifteen years old three-fourths adult dose should be used; in from nine to twelve years old one-half the adult dose; from five to nine, one-third the adult dose; children two to five, about one-fourth the adult dose; infants, from one-eighth to one-sixth dose. Individuals overweight may be given larger doses, or underweight smaller doses. There being no untoward after effects the dosage should be held pretty well up to the maximum.

Administration.—Inject subcutaneously near the insertion of the deltoid, using the same technique and aseptic precautions ordinarily used in hypo-

dermic injections. The injections should be started as early as possible and repeated every six, eight, or twelve hours till the maximum afternoon temperature is within 1° to 1.5° of normal, then given in one-half doses until the temperature reaches normal.

If the patient has a little rise of temperature in the afternoon, after it had been normal at this time, give one-half to one dose every twelve or twenty-four hours until the afternoon temperature again reaches normal. If it falls so far below normal that the patient is uncomfortable it is well to use a warm-water bottle. The subnormal temperature is the only reaction experienced, and this is of only minor importance.

Mode of Action.—When given hypodermically it is taken directly into the circulation of the individual. During the first two weeks of a typhoid infection almost all the typhoid bacilli forming the infection are in the blood of the infected individual. Emetine hydrochloride entering the blood forms a medium in which the typhoid bacilli cannot grow, as shown in the goat test. Consequently the typhoid bacilli in the circulation are killed. The typhoid bacilli being killed the cause is thereby removed and the fever ends. Here is also obvious why it is necessary to administer early. After the first two weeks the bacilli are numerous in the intestinal lymph follicles and are more difficult to reach, taking four to six days, while during the first ten days, when the bacilli are principally in the circulation, it takes from two to four days, depending on the time required to bring the blood up to a medium of about one to twenty-five thousand. To hold the medium about this point it is necessary to repeat the injection every six, eight, or twelve hours, as was said in the section on administration, as the emetine is rapidly eliminated by the kidneys.

Accessory Treatment.—A little calomel or calomel and phenolphthalein may be used to keep the bowels acting mildly, when used early. The same precautions should be taken relative to diet as is necessary in prolonged cases.

Caution.—Give as early as possible. If typhoid is suspected do not wait for a positive Widal. If it is typhoid the Widal will as a rule be positive later. Early use saves the patient much time and minimizes the danger of the disease, and late use may cause severe hemorrhage. I am convinced that emetine hydrochloride should not be used as an abortant of typhoid fever after the beginning of the third week unless used in very small doses, because of the results of its action.

When the typhoid is aborted, the ulcers clean off. After the beginning of the third week the ulcers are so extensive that their sloughing opens blood vessels and causes hemorrhages.

True, emetine hydrochloride is highly recommended as a hemostatic, and justly so; but the slough opens vessels large enough to cause serious hemorrhage if given late. I have never seen a fatal hemorrhage following its late use. If it is given in small doses after beginning of the third week it acts favorably but slowly, even in the third week.

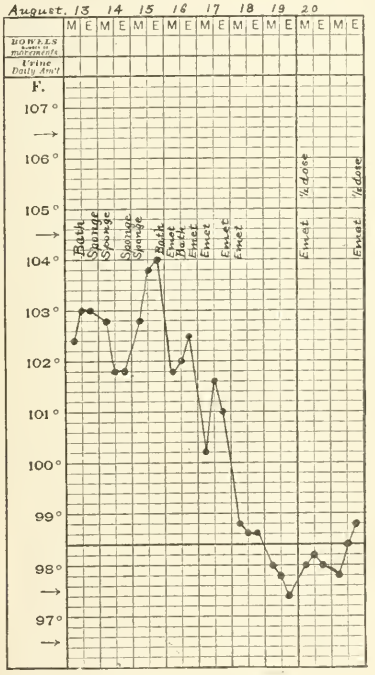
Here are given two cases of typhoid fever selected from a series of eighty-two. These two are typical cases of the series.

Case I.—Mr. R. B. R., age 37, gave a history of generally good health prior to present illness. On December 3, 1913, he had a slight headache. He took a course of calomel on December 4, but without relief. He was first seen on December 7. At this time he gave a history of frequent evacuations of the bowels and some tenderness in the abdomen. The fecal matter discharged was thin and light green in color.

For several days previous to the time of the beginning of the headache he had a feeling of malaise, with loss of appetite. His tongue was heavily coated and his breath foul, his temperature was 102.8° at 2 P. M.; at 6 P. M. 103.8°. He was given another course of calomel on December 7, which acted well. December 8, at 8 A. M. his temperature was 101.6°; at 12 A. M. 101.8°; at 4 P. M. 102.4°; at 8 P. M. 102.4°. December 9, at 8 A. M. his temperature was 102°; at 12, 103.8°; at 4 P. M. 103.8°; at 8 P. M. 103.6°. Typhoid was strongly suspected. A physician was called in consultation and he confirmed the diagnosis. At the beginning of the second week the Widal was made and was characteristic of typhoid.

The abortant treatment was begun Dec. 9, at 8 P. M. An injection was given every twelve hours from Dec. 9, 8 P. M. to and including Dec. 11, at 8 A. M., Dec. 12, 8 P. M., Dec. 13, 8 P. M. and Dec. 14, 8 P. M.

On Dec. 10, the temperature range was from 102.4° at 8 A. M. to 103.6° at 4 P. M. On Dec. 11, the highest was 101.5° at 8 A. M., the lowest 100.4° at 8 P. M. On Dec. 12, the range was from 98.4° to 99.1°. On Dec. 13, from 96.8° to 98°. On Dec. 14, from 96.8° to 97.2°.



Temperature Chart of Case II.

The patient made an uneventful recovery, with a rapid convalescence.

Case II.—M. F. D., age 25. Previous history good. About August 6, he began to feel badly, was first seen Aug. 12. Had a headache with increasing severity, and more severe in the afternoon. Constipated, appetite failing, malaise, weak, and generally indisposed to perform his daily duties. The physical findings were slight tenderness over the abdomen, coated tongue, slight skin rash, rose spots on abdomen, temperature 102.4°. He gave a history of having taken purgatives and quinine without any benefit. Typhoid was suspected and patient was put to bed and observed. The chart shows the variations of temperature and the influence upon the same of emetine. There was no fever after August 18 due to the typhoid. The very slight rise of temperature noted on August 21 was the result of faulty elimination.

PROPHYLAXIS OF PUERPERAL CONVULSIONS.*

By STEPHEN H. BLODGETT, M.D.,

BOSTON, MASS.

During the latter part of 1910, when I was following out the investigations embodied in my paper published in the Medical Record of January 13, 1912 (and of which this is more or less of a continuation) it occurred to me that possibly we could go one step further and find some method by following which we could prevent a case of pregnancy coming to the point where the induction of labor was necessary because of threatened convulsions.

With the kind cooperation of the maternity staff at the Massachusetts Homeopathic Hospital, I decided to put to the test a theory regarding the possible cause and prevention of convulsions, which had occurred to me while watching the maternity cases from the kidney standpoint, during the previous three years.

The theory which I had formed regarding the cause of the convulsions would be of very little interest to you, so I will omit it, and only mention what changes were made in the diet and treatment of the prospective mother, and the results obtained.

The changes consisted broadly in watching carefully the amount of urea excreted by the kidney, and when this fell below what appeared to me to be normal for the patient, in at once withdrawing all meat and fish from the diet.

The problem which I was trying to solve was to find some efficient method of examination so simple that it would be readily performed by the average physician, and one that would enable him to foresee the likelihood of convulsions, and when foreseen use some simple means to prevent them.

The rule was made that cases applying for admittance to the hospital for their confinement should eat meat but once daily, and bring a sample of the twenty-four-hour urine to the hospital every three weeks up to the sixth month of pregnancy. After that time the urine was to be sent in every two weeks. Any patient showing a slight subnormal urea output was ordered to send in the urine each week, and if the decrease still persisted she was to be notified to come into the hospital, where the urine could be examined each day and the diet regulated as we judged advisable.

It was very hard in many cases to persuade the patients to bring the urine as requested, and it necessitated constant work by the maternity internes to get many of the applicants to comply with the rules, and even with their utmost endeavors many of the cases failed to report as often as the rules required.

I may be criticised in these cases for not having performed the total nitrogen test on each specimen of urine, but that test is such that the average physician cannot perform it readily, and in following out my theory I was interested to see what results could be obtained from the estimation of the amount of urea excreted.

The figures which I present are from a very large number of cases. In fact, I think the number so large (over 1,500 confinements) and the period (two years) so long that whatever the theorists may say the results as shown by the statistics prove at least the efficacy of the treatment.

Taking our figures in 1909 and 1910 (see Medical Record of January 13, 1912, "Toxemias of Pregnancy") it seems fair to assume that about 2 per cent. of the usual run of hospital confinements develop convulsions, exclusive of those cases which we should classify as the emergency cases of convulsions. I have included in this latter class only those cases that were never seen by anyone connected with the maternity staff until sent to the hospital by the district or some other physician because convulsions had already taken place.

The following are the figures:

	Confinements	Convulsions	Induced Labors
For 1912 there were	768	2	1
For 1913 there were	890	2	0

I have excluded from these statistics the emergency cases of convulsions and the induction of labor in any of these emergency cases. I have excluded from these figures also a few cases brought to the hospital and attended by their own physicians who were not on the maternity staff. These casese were not subject to the maternity rules and consequently did not come under my supervision.

Perhaps I can best illustrate the way the work has been done by citing several of the actual cases.

Case I.—On August 12 Mrs. X applied for admission. Expected confinement was about January 1. The first urine sent in was on September 16. The uranalysis showed:

Date	Amt.	Sp.Gr.	Total Solids	Urea	Albumin	Sediment
Sept. 16..	470 c.c.	1022	24	7	Trace	
	Advised to eat meat but once a day; had been using it two and three times.					
Sept. 28..	1415 c.c.	1008	26	9.9	Sl. Tr.	
	Advised to enter hospital. Entered hospital Oct. 11.					
Oct. 13...	950 c.c.	1911	24	6	Sl. Tr.	
	Advised no meat or fish. Urinalyses were made daily.					
Oct. 18..	1415 c.c.	1014	46.5	17	V. Sl. Tr.	
	Allowed to leave hospital and advised to continue on a meat-free diet.					
Oct. 26 .	1280 c.c.	1011	33	14	V. Sl. Tr.	
Nov. 2..	860 c.c.	1016	32	12	Sl. Tr.	
	She was again advised to enter hospital as I felt the urea was getting too low. She came in November 4 and was put on a meat-free diet.					
Nov. 6..	1260 c.c.	1012	35	14	Trace	
Nov. 9..	1300 c.c.	1016	49	17	Trace	
	She was discharged Nov. 11, and advised again to continue same diet.					
Nov. 16..	1260 c.c.	1011	36	9	Sl. Tr.	
	Advised to reenter hospital, which she did Nov 19 and she was immediately placed on a meat-free diet. I have always felt that this patient while at home indulged more or less in meat, as each time she returned home her urea output decreased and on her admittance to the hospital where we could be certain she received no meat, her urea elimination would increase at once.					
Nov. 21..	540 c.c.	1018	22	9	Trace	
Nov. 23	2280 c.c.	1010	52	18	Trace	
	Although the albumin had increased to a trace she was discharged Nov. 24 and cautioned very strongly in regard to meat.					
Dec. 4..	1680 c.c.	1013	50	18	V. Sl. Tr.	
Dec 10 .	1200 c.c.	1018	50	16	V. Sl. Tr.	
Dec. 19 .	1680 c.c.	1014	51	15	V. Sl. Tr.	
	Patient was admitted on Jan 1 and was delivered on Jan. 2 of a healthy child. Mother and child made an uneventful convalescence.					

Case II (60,938).—Admittede to hospital July 16. At her first application she complained of headache, blurred vision and epigastric distress. She was placed at once on a meat-free diet and analysis of the urine the following day showed:

Date	Amt.	Sp.Gr.	Total Solids	Urea	Albumin	Sediment
July 18..	1320 .c.	1010	30	11	Sl. Tr.	
July 19..	1320 c.c.	1008	25	16	Trace	
	The urea output was increased relatively in considerable amount and it was considered advisable to carry case along without inducing labor.					
July 29.	1920 c.c.	1011	48	19	Sl. Tr.	
	The woman was delivered of a healthy child Aug. 5 and made an uneventful convalescence.					

This case typifies some of the cases where the clinical symptoms of impending convulsions were present, but in spite of these with proper treatment ended in normal labor.

Case III (62,427):

Date	Amt.	Sp.Gr.	Total Solids	Urea	Albumin	Sediment
Sept. 28..	480 c.c.	1014	15.5	8	Sl. Tr.	Many gran. casts
	She was advised to enter hospital, and did so Oct. 7.					

*Delivered before the Massachusetts Surgical and Gynecological Society, Dec. 10, 1914.

Oct. 9..	1800	c.c.	1010	41	S	Tr.
	She was put on a meat-free diet and despite amount of albumin and casts, the induction of labor was advised against.					
Oct. 12..	3600	c.c.	1004	36	21	Sl. Tr
Oct. 14..	2820	c.c.	1004	26	12	Trace
	Discharged Oct. 16.					
Oct. 19..	1440	c.c.	1015	50	23	Trace
Oct. 22..	1440	c.c.	1011	36	15	Trace
	Was delivered Oct. 23 of a healthy child.					

There was one case in my private work in which my advice was sought where we found albumin varying from 15 to 25 per cent. bulk. The prospective parents were exceedingly anxious to have a child, if possible. When the patient was taking an absolutely meet-free diet the urea would remain as high as 12 to 15 grams a day, and as the fetal heart beats remained strong I advised against the induction of labor, with the result that the patient about four weeks later was delivered of a healthy boy and had an uneventful recovery.

I will not take any more of your time by quoting cases, but will add that in many cases I have not considered the symptoms sufficiently urgent to necessitate the patient's entering the hospital, while in others it has seemed best to have the patient under daily supervision as regards diet and examination of the urine. Let me here add that in no case were there any ill effects where the termination of pregnancy was advised against.

It may be said possibly that these cases which I have instanced might not have gone to convulsions if allowed to go on with the ordinary diet, but I think it is perfectly fair to assume that the statistics of 1909 and 1910 showing convulsions occurring in 2 per cent. of the confinements, and this figure being reduced suddenly to less than one-tenth of 1 per cent. for the period of two consecutive years, during which we were testing our theory, without any other change being made, is due to the dietetic change.

In giving an opinion regarding each of these cases I have considered of first importance the amount of urea excreted daily and only secondarily the clinical symptoms and the amount of albumin present.

I have advised against the termination of pregnancy where the urea output has been normal, or where by giving a meat-free diet we could secure a normal urea output, and have given but very little consideration in deciding the question of possible convulsions to the amount of albumin present in the urine or to the clinical symptoms, and we have been rewarded with the natural birth of healthy children without any convulsions in the mother.

What can be learned from our two failures in 1912 and two in 1913?

In the first case, 1912, I examined the urine as a private patient in August. After two analyses, on account of low urea, I advised her physician to have her enter the hospital for observation, but she refused to come. After further analyses in September I again advised her admittance to the hospital as the urea was still low and the albumin was increasing. She once more refused, saying she felt well. On October 1 she was admitted to the hospital with a smoky urine containing 40 per cent. bulk albumin. Convulsions followed almost immediately and the patient died the next day.

In the other case the woman applied at the hospital April 11, and on April 16 she sent a sample. This on analysis showed Sp. Gr. 1010, urea .7 of 1 per cent. and a slight trace of albumin. The urea being relatively somewhat low she was notified to send the urine in again in a week. Nothing was heard from this case, however, until she was admitted June 19, labor having commenced when she appeared at the hospital complaining of vomiting, puffiness of the feet, and frequent headaches. She had four convulsions, but made a good recovery. The child died when a week old.

The first case occurring during 1913 was of an unmarried girl, who applied October 23. Her expected confinement was to be Nov. 25. Urine of October 29, 2800 c.c. Sp. Gr. 1014, total solids, 92 grams, urea, 37 grams, albumin a slight trace. Another analysis was ordered for November 12, but no urine was received. The next seen or heard from the patient was when she was admitted Nov. 24 already in convulsions.

The second patient applied Dec. 4. The specimen of urine Dec. 7 showed 1200 c.c., Sp. Gr. 1015, total solids 41 grams, urea, 16 grams; slight trace of albumin. Another specimen was ordered in two weeks. Nothing was seen or heard from the patient until she was admitted already in labor on Jan. 5. She was delivered at 3 A. M. Ether was given during the second stage. She had a convulsion at 5 A. M., and died at noon.

The two cases occurring in 1912 only serve to strengthen my belief that my theory was correct, and the two in 1913 made me more strong in my feeling that the urine should be examined as a routine procedure once a week during the last two months of pregnancy.

So far as medicine is concerned there has been no general rule in regard to the cases. Very few of them have received any medication whatever, and medicine has been given only where necessary to keep the bowels in normal condition.

It has been very interesting to notice how maternity patients on an ordinary mixed diet, with the urine showing an abnormally low urea output (although eating meat sometimes two or three times a day), would have a very decided increase in the urea output when the meat was eliminated from the diet. This increase will persist sometimes for several days. I have also found that nitrogen taken in other forms, as in milk or eggs, will not cause the same disturbance as the nitrogen from meat. Nevertheless, we have not increased the amount of nitrogen in the patient's diet where we have found it necessary to take away meat. The rule has been to allow the patients the same diet as they have previously been taking, with the exception of meat and fish.

From my experience in these cases I have come to the point where I have felt it safe to advise the continuation of pregnancy (the case being under constant supervision), even where the patients have headache, dimness, or blurring of vision, and a large amount of albumin, provided the excretion of urea does not go below normal.

I want to impress very strongly on you the fact that this theory has not been put to practical test for such a length of time that I can advise others to give up *all* consideration of the amount of albumin and the other clinical symptoms of impending convulsions, in deciding the question whether to terminate pregnancy or not.

I will report to you one case which occurred last week while I was writing this paper:

This patient had had twelve children, and she expected to be confined about the 5th of December. It was what might be called an emergency case, having been sent to the hospital on account of complete loss of sight in one eye. There was edema of the legs, intermittent headaches, great loss of vision, systolic blood pressure of 200. The uranalysis of November 24 showed 887 c.c. Sp. Gr. 1019, total solid 39 grams, urea 19 grams, very large trace of albumin. Sediment contained renal cells, blood discs, and hyaline casts, many of them having coarse granules adherent. The examination of the eyes by Dr. Horr showed right eye, choked disc, with a swelling equal to three or four diopters; left eye, vision not much affected, with a slight haze over the optic nerve. The uranalysis was made daily. The amount of urine increased and the amount of urea increased somewhat. I advised against inducing labor unless the elimination of urea should begin to decrease. The patient went on in the same gen-

eral way, taking the regular diet from which meat and fish were rigorously excluded. Labor began naturally on Dec. 2 and normal delivery followed. Patient and child are both doing well.

In conclusion I would say:

1. The work during the past two years has demonstrated that careful watching of the urea output, and making necessary changes in the diet will enable us to carry safely to the natural termination of pregnancy many cases which would otherwise go on to convulsions, or necessitate the induction of labor.

2. That the clinical symptoms are of secondary importance to the urea output in foretelling the probability of convulsions.

3. That the amount of albumin in the urine in a case of pregnancy is of secondary importance as regards the probable occurrence of convulsions.

4. That with proper and persistent prophylactic treatment puerperal convulsions may be prevented, but after convulsions have occurred the question is of more serious moment.

5. That to be on the safe side an examination of a sample of the twenty-four-hour amount of urine should be made every two weeks, in cases of pregnancy from the third to the sixth month, and once a week during the last three months.

6. I would consider that a pregnant woman whose physician does not keep careful watch of the urine after the third month would be in less danger of convulsions if she stops eating meat or fish during the last six months of pregnancy.

TWO MONTHS' SERVICE IN A SMALL HOSPITAL.

By ARMITAGE WHITMAN, M.D.,

NEW YORK.

THIS article has been written on the advice of several older surgeons, who felt that the experience of a young man exchanging the position of house surgeon in a large New York hospital for the further responsibilities and independence of a smaller semi-rural institution might be worth recording.

The writer was on the last two weeks of his service when he received an offer of the position of locum tenens from a surgeon of a very large town and country practice, the position carrying with it the office of attending surgeon to the local City Hospital. The hospital was of about eighty beds, practically all surgical, and the service under ordinary conditions amounted to between twelve and fourteen hundred operations a year. The offer was promptly accepted, and about the first of July the writer arrived on the scene of action armed with desperate resolution and Jacobson and Rowland's Operations of Surgery. One day was spent in watching the surgeon operate, and in becoming familiar with the cases then in the hospital. On the following day the surgeon left for his vacation.

While nominally the City Hospital, the institution was run by a sisterhood, which furnished a Sister Superior, corresponding to the ordinary superintendent, and a sister in charge of the operating room and of each ward. The other nurses were furnished by the pupils of a small training school, the head of which was also one of the sisters. Although, as it was summer, many of the nurses were on their vacations, one gained the impression that there might well have been more nurses if the work on hand were to be handled in the best possible way. The training received by the pupils was as good as it could have been under the circumstances, but naturally according to the ideas of one man alone, and there was so much routine ward work to be done that the sister in charge usually took entire care of the sick cases, while the pupils, instead of being thereby instructed, were solely employed in waiting on the convalescents. The charts kept were of the most meager variety—mouth temperatures taken twice a day, with pulse and respiration. Stools and urine were never recorded. Medication was supposed to be ordered by the attending in writing, as it was, when he desired anything out of the ordinary, but as a matter of custom all postoperative treatment, such as cathartics and sedatives, was left to the sisters. This method may have worked perfectly as a rule, but, as has been mentioned, vacations were playing havoc with the regular staff of both sisters and nurses, and cathartics and sedatives were given by spasms. The writer was once accosted by a hernia patient in the following heart-rending terms: "Doc, I've been in the hospital ten days. My bowels have moved twice, and it's taken two ounces of castor oil each time to do it. Say, Doc, can't they be a little more regular?" In another instance, arriving very early to inquire the state of a patient with acute intestinal obstruction operated on the day before, for whom no orders had been left, the writer was told that the patient had had a terrible night, requiring several hypodermics for relief. No one could be found who knew how much morphine had been given, or, for that matter, why it should not have been given in that particular case.

A comparison of the personnel of the operating room which the writer left with that of the one to which he came might here be of interest. His own hospital: (1) Attending surgeon; (2) assistant surgeon, interne; (3) second assistant surgeon, interne; (4) anesthetist, interne (or special anesthetist, in which case the interne anesthetist was available for third assistant if desired); (5) head nurse in charge of operating room; (6) pupil nurse, assistant to head nurse, making two nurses at the instrument tray; (7) pupil nurse, on call from the operating room, ready to give hypodermic stimulation, get extra instruments, etc.; (8) orderly in the operating room; (9) occasionally extra orderly on call in special cases. Instruments were gotten out by the head nurse, who knew unfailingly the individual preferences and operative routine of the various operators. The instrument tray was arranged according to an unvarying plan, and each instrument after being used was picked up by the assistant nurse, cleaned, and returned to its proper place on the tray. If, therefore, by any unhappy chance, the house surgeon did not have the proper instrument ready to the operator's hand, the operator knew where to get it without looking for it. Certain knots, determined by unvarying routine, were tied by the assistant, and all sponging was done by him. The second assistant held retractors. The patient was lifted to and from the table by the anesthetist, orderly, second assistant pupil nurse, and second assistant surgeon, whose sterile hands were protected by a towel as he seized the patient's feet. The nurse then removed the preliminary dressing, the second assistant scrubbed the skin, and then retired and washed his hands a second time while the patient was being draped by the head nurse. The operator and first assistant did nothing until the time came to make the incision.

At the City Hospital the personnel was as follows: (1) Attending surgeon; (2) graduate nurse, acting as first assistant, who did the sponging; (3) pupil nurse, who held retractors, or passed instruments, whichever seemed at the time most urgent; (4) anesthetist, sister in charge of the operating room, who gave any necessary orders to the nurses, got out extra instruments, etc.; (5) unsterile pupil nurse; (6) orderly, who was not allowed in the operating room after he had helped to lift the patient onto the table. The routine was somewhat after this order: While the sister was starting the anesthetic the attendant gave his hands a preliminary scrub. When the patient was wheeled into the room, he, with the orderly's assistance, lifted him to the table. He then removed as much of the night shirt as seemed necessary, scrubbed the skin with benzine and iodine mixed, and when that had dried, applied iodine to the field of operation. The graduate nurse and anesthetist then draped the patient while the surgeon gave his hands the final scrub. During the operation he tied all knots, and if he laid down an instrument woe betide him if he forgot where he put it. Sutures and ligatures up to a certain number were laid on the tray, but never handed, and if he wanted extra ones, he must break the tubes himself. He got out his own instruments, and if in the midst of an operation anything were missing there was no one to blame but himself. When the operation was over he lifted the patient from the table, and with the orderly took him back to the ward. These were normal conditions, but, as has been said, it was then summer, the regular sisters and nurses had to have vacations; the regular attending surgeon was away, and what better time could there be to paint the operating room and repair the elevator? For over a week the writer and the orderly carried sick patients upstairs and all patients downstairs; the first case of ruptured urethra was operated on in the anesthetizing room at 10 P.M. by the light of one small bulb in the ceiling, because the operating room was being painted; and the first case of strangulated hernia with resection and enteroenterostomy occurred while the graduate assistant was on vacation, and was done with the assistance of a pupil nurse who had never before assisted at any operation.

As for the laboratory side, it was left entirely to the discretion of the attending. All such urine examinations as were thought important he did himself. Blood counts he had tried, and found mostly unnecessary, except in rare blood conditions. The writer took his own apparatus, and did some for his own peace of mind, but as time went on the number of white and differential counts done in acute surgical conditions grew fewer. The cystoscope the writer was unable to use, and fortunately but one case occurred—tuberculosis of the kidney—in which he felt really uneasy without it. The *x*-ray, as he was not an expert, he was requested not to use, and was thus left dependent on a small fluoroscope, which, to his untutored eye, was practically of no use at all. This was undoubtedly the greatest deprivation, as there were a large number of fracture cases in which the *x*-ray would have been of the greatest value.

The last and greatest difference between the two the discretion of the Attending. All such urine exwriter had enjoyed to the full the ephemeral grandeur of his position. Few patients could enter the hospital without his permission; his orders, while actually the attending's, were nominally his own; patients and nurses were obsequious to a varying degree; and the amount of responsibility accorded him was just enough to convince him that recoveries of doubtful cases were due to his personal efforts and unremitting post-operative care, while the rare deaths were acts of Providence visited through the unfortunately errant hand of his attending. His own operative cases all got well, or perhaps one or two were carried off by pneumonia, "that friend of the aged." Such a halcyon existence he exchanged for a world where the patients were wont to use some such address as the following—a laborer, for instance, fresh from his ditch, "Say, Blank here? Gone away? You're the feller he's left? Well, my woman's pretty sick, but I guess I'll wait till he gets back." Democracy reigned supreme, but it must be said that gratitude was quite as much in evidence as in places where the use of titles of respect were more in vogue. The sisters were kind, but it was always to be borne in mind that there was but one real doctor in the world, that that one was "Doctor," that he was far away, and that there were none but his methods. This fact was tactfully explained to the writer about his third night, when he was so unfortunate as to order an immediate operation on an acute appendix at 10 P.M. He noticed that the nurses seemed astonished, and that the preparations took much longer than usual, and finally when the sister in charge stumbled sleepily in, he was taken to task for operating after six. He explained that it was an acute appendix, and shortly proceeded to produce a gangrenous one in what he supposed would prove his triumphant vindication. The sister was kind enough not to say anything more at the time, but later "Yes," she said, "I saw it was an acute appendix, but somehow Doctor always seems to know just what cases will wait over till morning. Why, I don't believe he's operated once at night for two years. But of course we don't expect that amount of judgment from a young man—not but what you may be just as good when you get to his age." The statement as to night operations was something of an exaggeration, as was proved by further inquiry from impartial sources. The feeling that prompted it, however, remained unchanged for some time. Another and more striking instance was shown some time later, when the writer was called to the hospital to attend a man whose femoral vein had been severed by the mud-guard of an automobile. As it had not occurred to any of the intelligent bystanders to search for the source of the hemorrhage and stop it, the patient was practically dead when he reached the hospital. An infusion was ordered at once, but no apparatus was available, and by the time a hypodermoclysis had been started with a douche bag and other improvised accessories the patient was dead. The surgeon was much annoyed at the delay in providing such emergency remedies, but when he laid down the axiom that such things should always be ready for instant use, he was told that Doctor never used them. On the inquiry as to just what Doctor would have done in such a desperate hemorrhage the commiserating answer came pat—"Doctor would never have brought such a case up to the operating room."

Needless to say, after two such sharp lessons the writer made no further effort to wrestle with the feminine intelligence, but from that time on any deviation from routine had to be carried out with his own hands, and its continuance made the subject of eternal vigilance. As an instance, he was struck with the persistent manner in which the binders on abdominal cases refused to stay in place, and suggested the use of perineal straps to remedy

the defect. Although he repeatedly demonstrated in the wards the way in which the binders slid up and left the dressing unprotected, apparently to the logical satisfaction of his audience, and requested that straps be applied to all binders, they were never used except when applied by him in the operating room, and even then were never reapplied when the binders were changed. But except in such small matters as these the sisters were kindness itself, and it is extraordinary how quickly one may become accustomed to being regarded as an amiable lunatic.

Dressings were done with unsterile rubber gloves washed off, as were the instruments used, with lysol. Sterile towels to protect the surroundings were unknown, a state of affairs that at first roused the most gloomy forebodings, but in spite of their absence infection of clean cases did not occur, and the results of operative and postoperative technique in regard to asepsis were thoroughly satisfactory. The fact that most impressed the writer during the whole two months was the lack of postoperative discomfort, and the speed with which all the patients got well. Whether this was due to the difference in mental make-up between city and country patients, or to the difference between city and country air he was unable to determine, but a second dose of morphine was decidedly the exception, postoperative distention was very slight, and pneumonia did not occur. The anesthetics, by the way, were all drop ether, adults being given a preliminary dose of morphine and scopolamine when possible.

Classification of the cases is as follows:

Acute appendicitis, 16 cases, of which 6 were drained;
Chronic appendicitis, 8 cases;
Cholelithiasis, 3 cases, in two of which the gall-bladder was removed;
Acute suppurative cholecystitis, 1 case;
Inguinal hernia, 2 cases;
Femoral hernia, 1 case;
Strangulated inguinal hernia, with gangrene of 36 inches of ileum, 1 case;
Hypertrophy of prostate, 2 cases (suprapubic prostatectomy);
Epithelioma of mandible, 1 case (2 stage operation, first removal of all glands and internal jugular vein on the affected side; two weeks later removal of the ramus of the mandible);
Rupture of male urethra, 2 cases (in one of these suprapubic lithotomy and retrograde catheterization was necessary);
Tuberculosis of kidney, nephrectomy, 1 case;
Tuboovarian abscess, salpingo-oophorectomy, 4 cases;
Strangulated ovarian cyst, 1 case;
Tuberculosis of cervical lymph glands, 3 cases;
Acute intestinal obstruction from a band, 1 case;
Fracture of patella, open reduction and wiring, 1 case;
Traumatic lateral ventral hernia, 1 case;
Miscellaneous, 34 cases.

Of these cases one patient died—a man 74 years old, suffering from hypertrophy of the prostate with acute retention, cystitis, arteriosclerosis, chronic nephritis, etc., who found his condition so unbearable that he insisted on being operated on, contrary to the advice of the surgeon. Several days were spent in trying to improve his condition, without much success, and he died 24 hours after the operation from suppression of urine. The first case of ruptured urethra, in which suprapubic lithotomy was done, progressed satisfactorily until the third night after operation, when, in spite of its having been sewn in place, the night orderly pulled out his retention catheter. It was impossible to replace it, and as the patient was over 60 he refused further operative interference at the time, preferring his suprapubic fistula. The cases, at least as far as the writer was able to ascertain at the time of his departure, had all done well.

The lessons learned by the two months' experience were of course many and of great value. Older men know them. House surgeons of the immediate past and future, however, are adjured by one of them who has suffered, to do without, at least in their preliminary diagnoses, those special aids of which the author was deprived—or better still, to become familiar with their technique. In conclusion he wishes particularly to emphasize the fact that his article has been written entirely with a view to comparison, not to criticism, and that he is very happy to acknowledge that many of the simple methods which he at first was inclined to term barbaric were productive of quite as good results as any that he had obtained by possibly more scientific, but certainly more complicated procedure.

283 Lexington Avenue.

A CANNULA AND NEEDLE FOR BLOOD TRANSFUSION AND INTRAVENOUS INFUSIONS.

By DAVID J. KALISKI, M.D.,

NEW YORK.

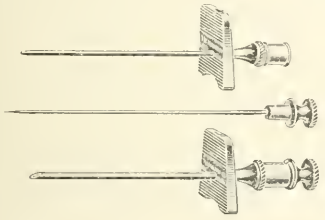
Blood transfusion by the indirect method can be greatly facilitated and simplified by the use of properly designed and constructed cannulas or needles. It is the purpose of this brief communication to describe the apparatus used by the author for blood transfusion and to draw attention to the fact that by the use of cannulas or needles of the type under consideration it is possible to aspirate or inject blood by direct introduction of the apparatus into the vein without the necessity of exposing the vessel. Tiny or marantic infants offer possible exceptions. In these it may be necessary to expose the jugular or one of the cubital veins. In the experience of the author and his associate, Dr. Ottenberg, the introduction of the cannula into the vein of the donor or patient represents the greatest problem in technique of the operator using any of the indirect methods of transfusion. Inasmuch as doing away with the necessity of an incision has been a great factor in popularizing such methods, the use of, and familiarization with, an instrument of the type to be described and illustrated is apparent. Once the cannula is properly and securely introduced into the vein the remainder of the procedure presents no difficulty.

The cannula is constructed like an ordinary aspirating trochar and cannula, with the exception that the trochar point is rounded and fits the cannula perfectly and snugly so that there is practically no collar at the point of junction of the two, thus offering no resistance to the smooth introduction of the instrument through the skin into the vein. There should be at least from three-sixteenths to one-quarter of an inch protrusion of the trochar from the tip of the cannula. This is for the purpose of making an adequate puncture through the skin. The instrument must be made with the greatest care and of the hardest steel, so as to assure a sharp cutting point. The cannula pierces a bridge

of heavy steel which raises the cannula-hub sufficiently far from the skin to permit of the coupling of the syringe and its detachment without disturbing the position of the cannula in the vein. This is a factor of great importance since in a transfusion by the syringe method popularized by Lindeman, the introduction of, say 500 c.c. of blood, requires this manipulation at least twenty-five times. The bridge also acts as a support in obtaining a firm grip in inserting the apparatus and holding it in position afterwards.

The cannulæ vary in length from two to three inches and in caliber from 13 to 16 gauge B. & S. The hub is made to take the regular Record syringe point, or any other tip may be used by means of a coupler that can be slipped on the syringe tip. The finer caliber cannula is used in women and children, or men with small veins, the larger ones for the donors or for the patient, if the size of the vessel permits. One liter of blood can be transfused through the smallest cannula without difficulty. The author has transfused with ease as much as two liters through the medium sized cannula.

The cannula is also made with a cutting point, as illustrated. This needle is occasionally of use in donors with very thick skin or for the introduction of a very large sized instrument for phlebotomy or withdrawal of blood into an anticoagulating solution, for example, sodium citrate. It is rarely if



ever necessary to use the cutting point. The withdrawal of the trochar after the cannula has been freely introduced into the vein leaves a blunt-pointed tube *in situ* which it is exceedingly difficult to push through the posterior wall of the vein, through which a continuous stream of blood emerges while the constricting band is in place, and which will not easily be dislodged from its position.

Technical Suggestions.—A few points in technique suggest themselves here which it might not ba amiss to emphasize. The tourniquet should not be too heavy, a light-weight, soft-rubber catheter serving this purpose best. It should be applied only firmly enough to cause venous stasis; the pulse should not be obliterated. The vein should be filled up by milking or massaging the arm in the direction of the tourniquet, then the skin should be stretched in the axis of the vein to be punctured by grasping the forearm, for example, with the palm of the left hand under the arm, using the thumb to stretch, and fix or immobilize the vein. The cannula is then held so that the index and second finger bulbs of the right hand grasp the bridge, and the thumb bulb holds the cap of the trochar at the hub-end in place, and the cannula is firmly pushed through the skin into the vein. When the cannula enters the vein, there being no further resistance to its progress, it should be pushed into the lumen of the vessel at least an inch. When the trochar is withdrawn, if the needle is properly *in situ* in the vein there will be a free spirt of blood. If this point in technique is acquired, the aspiration or injection of the blood will offer no further difficulty. No attempt should be made either to aspirate or to inject until the cannula is free within the lumen of the vein, else there will occur an hematoma from the injection of blood into the tissues about the vein or a leakage of blood from the improperly punctured vessel if the tourniquet is left in place, as in the case of the donor. This will render the vein unfit for use and make another puncture necessary. Occasionally in introducing the cannula after the withdrawal of the trochar the blood issues only in a small stream or not at all. If the instrument is very slowly and gradually withdrawn without the trochar in place, blood may presently issue freely from the cannula, showing that the tip was occluded by a vein valve or by the wall of the vein. The operator should familiarize himself with the "feel" of a distended vein by developing the tactile sense. Large veins are occasionally deep seated at the bend of the elbow, especially in obese persons and children. The constricting band is left in place throughout the operation on the donor, being removed for a few moments should the arm become too deeply congested from too tight construction. In the recipient the tourniquet is removed as soon as the operator is certain the needle is properly introduced.

The cannulæ can be used for saline infusions, salvarsan injections, infusions of citrated blood by the method of Weil or of Lewisohn, and phlebotomies. They can be obtained from Tiemann & Co., New York City.

1070 Madison Avenue.

Medicolegal Notes.

Degree of Care and Skill Required—Admissibility of Evidence.—Action was brought against a physician and surgeon for alleged malpractice consisting of failure to properly reduce a dislocated hip for the plaintiff. It was a disputed question whether the dislocation was or was not properly reduced, and there was some evidence tending to show that the plaintiff about a month later fell and reinjured his hip. Several months after the treatment of the limb by the defendant an *x*-ray photograph was taken of the joint. The plaintiff insisted that the trial court erred in not permitting him to show to the jury the unsuccessful efforts he made to get the *x*-ray plates. The defendant had nothing to do with taking the photographs and never had possession of them. It was held that there was no error in the ruling of the court.

An instruction given for the defendant which defined ordinary care and skill required of physicians and surgeons as being "that care and skill exercised by physicians and surgeons in this locality and of the school of which defendant belongs" was held to be erroneous and misleading because of the insertion of the words "and of the school of which defendant belongs," thus limiting the care and skill required to that of some particular sect of physicians and surgeons in the locality. It was also held erroneous because there was no evidence as to what school the defendant belonged, except that he was a graduate of the medical department of the University of Illinois College of Physicians and Surgeons. Judgment for the defendant was reversed and the case remanded.—Bacon v. Walsh, 184 Ill. App. 377.

When Physician's Opinion Is Inadmissible.—In an action for personal injuries where the manner in which the plaintiff was injured was not disputed, it was held improper to permit physicians to testify as to whether the circumstances of the accident would have caused the injury, basing their opinion upon the testimony of the plaintiff as to how he had been injured.—Johnson v. Danville U. & C. Ry. Co., 185 Ill. App. 83.

MEDICAL RECORD.

New York, March 20, 1915.

DEVELOPMENTS IN SCARLATINA THERAPY.

WITHIN recent years there have been introduced in the treatment of particularly severe cases of scarlet fever two methods that offer considerable promise. One of these is the use of salvarsan or neosalvarsan; the other is the employment of the blood serum of convalescent scarlet fever patients. These methods are representative of the two main trends in the treatment of infectious disease, namely, chemotherapy and serum therapy.

Salvarsan was first employed in 1910 by Rumpel in three cases of scarlet fever but without success. Later Lenzmann, Klemperer and Waita, Lorey, Schreiber, and Jochmann employed the same drug and all seemed to agree that salvarsan has a favorable influence on the course of the disease, particularly in controlling the severe angina. The latest to investigate the merits of this mode of treatment is F. Poensgen, who reports his results in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. 3, Nos. 1 and 2. His experience comprises 35 cases which represented severe types of the disease. Salvarsan was administered intravenously in 30 of the cases, with positive results in 10, negative results in 15, and doubtful results in 5. In the 5 cases in which neosalvarsan was used the results were negative in all. There was no question that salvarsan saved a large percentage of the particularly severe cases of scarlet fever. In no instance could any unfavorable action of the drug be observed. Complications were, however, neither ameliorated nor prevented, a circumstance explained by the fact that these complications are the result of the action of streptococci which are apparently not affected by the salvarsan. Although of value in some of the severe cases of scarlet fever, salvarsan cannot be regarded as a specific against this disease.

The favorable results obtained by the use of the blood serum of patients convalescing from scarlet fever were first reported, on the basis of 12 cases thus treated, by Reiss and Jungmann. These results were confirmed in the similar management of 22 cases by R. Koch (*Münchener medizinische Wochenschrift*, 1913, No. 47). These cases were all severe ones, and death occurred only in one instance, in the case of a patient who was already in the agonal condition. Even in the late stage of the disease when the local streptococcal manifestations dominate the clinical picture, and in the septic type, a distinctly favorable influence is to be observed. This method of treatment was not responsible for the production of hemorrhagic nephritis.

The results thus far obtained in the treatment of scarlet fever by means of neosalvarsan or convalescent serum are sufficiently encouraging to warrant the further trial of these methods.

HYPERSENSITIVENESS AND IMMUNITY.

THERE is abundant evidence that hypersensitiveness and immunity are closely related to each other, but the significance of this relationship is as yet obscure. P. W. Clough (Bulletin of the Johns Hopkins Hospital, February, 1915) has performed a series of experiments to determine whether there is any constant relation between pneumococcus infection and hypersensitiveness to pneumococcus protein. Reference is made to the theory advanced by Friedberger, namely, that bacterial protein is broken up by specific ferments which are present in small amounts in normal individuals but which increase in amount when the foreign protein persists in the circulation. As a result of this there is a rapid decomposition of the foreign protein with the production of immunity or hypersensitiveness.

The real distinction between these two phenomena depends upon the following circumstance: If the foreign protein is one which does not increase after its introduction into the body, the rapid decomposition of the protein causes the production of poisons which may be fatal to the animal if the dose of protein is large. The animal is hypersensitive. If, on the other hand, the foreign protein is a living virus and increases in amount after introduction into the body, the accelerated action of the protective ferments is sufficient to destroy the invading microorganisms. If these are not too numerous, the poisons resulting from their decomposition are not sufficient to cause dangerous effects. The animal is immune. According to Friedberger the general symptoms of an infectious disease are the result of the intermediate poisons formed by the decomposition of the bacterial protein. The latent period following infection is attributed to the fact that symptoms are produced only after antibodies have been formed in sufficient quantity to cause a very rapid decomposition of the bacterial protein.

Clough obtained from pneumococci a protein extract which would sensitize normal guinea-pigs and intoxicate suitably sensitized guinea-pigs. The latter show inconstantly a very slight degree of immunity to infection with living virulent cultures of pneumococci. Animals highly immunized by repeated subcutaneous injections of the latter show on the other hand a marked degree of hypersensitiveness to pneumococcus extracts. Clough has not succeeded, however, in demonstrating this hypersensitiveness in pneumonia patients by the local application of a solution of the protein to the conjunctiva or by intracutaneous injections.

FOOT AND MOUTH DISEASE IN GERMANY.

We are having our own troubles in times of peace with the foot and mouth disease in cattle and the question has no doubt come into the minds of national economists of the significance of this plague in a nation at war. In Germany there is such a shortage of fodder that ten per cent. of all the milch cows will have to be killed. No absolute loss need result, however, for the beef can be cured in various ways, aside from the fraction which will be eaten fresh. But when foot and mouth disease prevails, herds would have to be sacrificed at a total loss—unless some of the meat and milk can be pronounced fit for human consumption. This possibility was thoroughly realized in Germany several years ago.

At one of the military medical evenings held during January at Berlin (*Berliner klinische Wochenschrift*, January 25) Schütz stated that Germany was pronounced free from foot and mouth disease in 1910, but the scourge was introduced anew from Russia. At first the border suffered, then East Prussia, and finally the other provinces. In 1911 the disease had reached its climax. The author assisted Koch in combating the epidemic and much knowledge of its nature accrued in the following year, which is incorporated in the most recent reference works. Measures were then devised to prevent total food and milk loss and these were in force long before war was declared.

The beginning of the war found cases of the disease throughout Germany. The Russians seized affected animals as booty, while von Hindenburg returned them to the Fatherland. Infected animals have thus been scattered throughout Prussia. To the domestic campaign is therefore superadded the problem of fresh arrivals from Russia. Germany has the two-fold problem of checking the spread of the epizootic and the salvage of food products. With the shortage of fodder it seems inevitable that the cattle to be killed off will correspond more or less closely with the most tainted herds.

NEW THERAPEUTIC MEASURES IN TYPHOID FEVER

The surgeons are not the only ones who are applying their resourcefulness in trying to solve the many important problems arising in the present war. The internists are also profiting by the vast amount of material at their disposal in the various military hospitals. Typhoid fever is the disease which as usual is engaging most attention in this respect. In the *Presse Médicale*, January 14, 1915, there appear two papers in which are reported new routine methods of treating typhoid fever. M. E. de Massary advocates the use of continuous refrigeration of the abdomen by means of an ice-bag, the skin being protected by a thick layer of talcum powder and a piece of light flannel. In conjunction with this measure there is enforced absolute rest, and the patient is given a large amount of water to drink. This method was employed in 140 patients with a mortality of 8.5 per cent. In the second paper E. Weil extols the use of the Murphy drip as an efficient procedure in combating typhoid fever. The solution used is a liter of water at 40°C., containing 50 grams of glucose. It has both nutritive and diuretic properties, reduces the temperature of the patient, and in other respects improves his condition. The nervous manifestations particularly are said to be relieved.

RUPTURE OF THE DIAPHRAGM FROM IMPENDING SUFFOCATION.

Professor Sauerbruch, the eminent thoracic surgeon, who was living in Zürich at the outbreak of the war and was at once placed in charge of the military hospital in Strassburg, was later transferred in the same capacity to conquered Lille. At a "military medical evening" in the latter city last December he reported a unique case (*Münchener medizinische Wochenschrift*, January 19), in which an erroneous diagnosis figured. An officer was buried under the earth in a trench. He was extricated and taken to the hospital in collapse with cyanosis and pulse hardly palpable. The expiration was of a peculiar forced character, occuring in impulses. Inspiration was superficial. On the entire left side tympanites of the highest type was present. The diagnosis seemed self-evident—rupture of the lung with tension pneumothorax. The term of survival is not mentioned, but operation was probably contraindicated by the general condition. Autopsy showed that while the lung had been torn there was an enormous rent in the diaphragm through which the strongly inflated stomach had entered the pleural cavity. The officer was 32 years old, and must have had an abnormally elastic thorax, for traumatic rupture of the normal lung should not occur at this relatively advanced age.

THE HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.

The Hospital Saturday and Sunday Association of New York City has done good work in the past, and the possibilities are promising that it will do even better in the future. Recently Dr. S. S. Goldwater, Commissioner of Health of New York City, delivered an address before the annual meeting of the association, in the course of which he suggested that the public would support a more comprehensive program. He pointed out that many problems were impending which would render it desirable that the hospitals should be so managed that they would fit in with the schemes of reform. He further drew attention to the fact that hospital statistics were neither complete nor adequate and suggested that in this direction the association should cover the entire field. The speaker particularly emphasized the urgency of the dispensary problem and was of the opinion that the association, with $50,000 or $100,000 in hand and with a clear conception of what dispensary work ought to be, should have no difficulty in persuading dispensaries to change their methods for the better. The address throughout was a strong plea to the association to endeavor to initiate some much needed reforms in the working of voluntary hospitals and especially of dispensaries.

INSANITY IN RELATION TO SEX AND AGE.

While neurasthenia, hysteria, and the other neuroses are more prevalent among women than men, it appears that insanity is considerably more rife among men than women. The Bureau of the Census of the Department of Commerce has published recently a report through William J. Harris, Director of the Census, prepared by Dr. Joseph A.

Hill. Without entering into details, it may be said that this report shows clearly that in a typical community of 200,000 persons equally divided as to sex 208 of the males would be found in insane hospitals and 200 of the females, and in the course of one year 72 males would be admitted to the hospitals, as compared with 60 females. Further, the number of males in hospitals for the insane has increased faster than the number of females. The chief reason for this state of affairs is said to be that, men being more addicted than women to vice and dissipation, the alcoholic psychoses and general paralysis are more common among men. Indeed, if the cases of insanity arising from these conditions were eliminated there would be little disparity between the two sexes. The conclusions to be drawn from the report are that putting on one side the cases of general paralysis and alcoholic psychosis, there are more cases of other forms of insanity among women than among men in the period of life from 30 years of age up to about 56, but fewer in early life and in old age.

News of the Week.

Red Cross Units for Belgium.—The American Red Cross announced last week that on request of Surgeon General De Page of the Belgian Red Cross, the organization will send to Europe for service with the Belgian Army two Red Cross units of three surgeons and twelve nurses each.

Disease Ridden Serbia.—A Berlin news agency states on the authority of Dr. Tinhoven, chief of the Netherlands Red Cross Mission to Serbia, who has returned home after a long stay in that country, that the military and civil population are suffering from violent epidemics of dysentery, typhus, and typhoid fever. Everywhere hospital conditions are piteously inadequate, and the country faces devastation worse than war. Sixty-three physicians have already died of typhus.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer of the committee, reports the following contributions received during the week ending March 13, 1915:

Dr. Frank Slopanskey, Helper, Utah	$5.00
McKees Rocks Medical Society, McKees Rocks, Pa.	6.50
Dr. James M. Anders, Philadelphia, Pa.	15.00
Dr. Charles M. Green, Boston, Mass.	25.00
Dr. J. M. Miller, Hickory, Pa.	5.00
Dr. John Woodman, New York, N. Y.	10.00
Dr. R. L. Bradley, Roswell, New Mexico	5.00
Dr. Everett D. Peek, Thompson Falls, Mont.	25.00
Dr. Charles L. Minor, Asheville, N. C.	15.00
J. M. H., Ft. Logan H. Roots, Ark.	5.00
Dr. Fred E. Thompson, Detroit, Mich.	25.00
Dr. Alfred H. Tickell, Nevada City, Cal.	2.00
Dr. Z. H. McClanahan, Colorado Springs, Colo.	5.00
Dr. C. Dunbar Roy, Atlanta, Ga.	5.00
Hempstead Academy of Medicine, Portsmouth Ohio.	10.00
Dr. Halsey Beach Loder Boston, Mass.	5.00
Dr. and Mrs. James R. Judd, Honolulu, Hawaii	25.00
Dr. Hugh T. Patrick, Chicago, Ill.	25.00
Receipts for week ending March 13	$218.50
Previously reported receipts	4,611.50
Total receipts	$4,830.00
Previously reported disbursements $4,614.60	
Disbursements week ending March 13, 90 boxes of food at $2.30 207.00	
Total disbursements	$4,821.60
Balance	$8.40

Resignation of the Health Commissioner.—It is reported that Health Commissioner Goldwater of New York City will retire on April 1, as his leave of absence as superintendent of Mt. Sinai expires on that date and his services are needed for the planning of an annex to the hospital. We hope the report is incorrect, for Dr. Goldwater has proved himself a most efficient health administrator and the city can ill spare him while there is yet so much to be done before all the reforms he has undertaken have been accomplished.

New York's Death Rate.—The mortality in Greater New York for the week ending March 6 was noteworthy by reason of the extreme low point reached by the death rate, namely, 13.91 per 1,000 of the population. This is an unprecedently low figure for this season of the year. The death rate for the first ten weeks of this year was 13.90 for 1,000 of the population, against 15.41 for the corresponding period in 1914, a decrease of 1.51 of a point.

Dr. Sidney Porter of New Orleans, who was elected State medical officer of the Louisiana Board of Health, at the December meeting of the Board, has resigned that office, giving as his reason that the duties conflict with his private practice.

A Law Against Division of Fees.—The Kansas Senate has passed unanimously a bill prohibiting surgeons paying commissions to physicians who may send patients to them, or advise patients to go to them for treatment or operations. However, the bill specifically states that it shall not be unlawful for the attending physician to receive a fee from the surgeon or specialist for services actually performed in case the patient is informed in advance as to the amount of the fee which the physician is to receive.

The United States Civil Service Commission announces an open competitive examination for mine surgeon. for men only. From the register of eligibles resulting from this examination certification will be made to fill a vacancy in this position in the Bureau of Mines, Pittsburgh, Pa., at a salary ranging from $2,400 to $2,700 a year. The duties of the person appointed to fill the position of mine surgeon will be to travel with the Bureau of Mines rescue cars and make a physical examination of all applicants for first-aid and mine-rescue training; to assist the Bureau of Mines first-aid miners in improving the technique of first-aid methods pertinent to mining and metallurgical accidents; to enter mines after fires and explosions for the purpose of taking blood samples and making other physical examinations of the victims before their removal; to make physicial examination of those engaged in mining and metallurgical industries to determine the effect, if any, of such occupations on the health and physical well-being of those employed therein; to examine the sanitary and hygienic conditions in and about mines and mining villages with a view of determining the effect of such conditions on the health and physical well-being of those engaged therein. Application should be made for forms 304 and 2095, stating the title of the examination, to the U. S. Civil Service Commission, Washington, D. C.

Appropriation for a Medical College.—The Oregon legislature has appropriated $50,000 for a new building for the University of Oregon Medical College and plans are being formulated to raise an equal amount from other sources so that at least $100,000 will be used in putting up the first unit of a building that will eventlly cost in the neighborhood of $350,000 to $400,000 and will accommodate 250 to 300 students.

Opposition to the Mayo Foundation.—The Hennepin County, Minn., Medical Society, at a meeting held March 1, adopted resolutions opposing the affiliation of the Mayo foundation at Rochester with the medical department of the University of Minnesota.

If the proposed plan is adopted, the resolutions state, "the university of the great State of Minnesota, perpetual in a sense, and destined if it may be judged by its past to a great future, will be hampered in one of its schools, possibly the most important one to the commonwealth by a private financial institution, successful, large, and powerful to be sure at present, but destined sooner or later as all experience of similar institutions shows, to deterioration."

The Interstate Association of Anesthetists will hold its organization meeting in conjunction with the Ohio State Medical Association in Cincinnati, Ohio, May 4 and 5, 1915, at which time an elaborate scientific program, devoted exclusively to anesthesia and analgesia, will be presented. Headquarters, assembly room, and exhibits will be in the New Hotel Gibson, in which all the sections of the Ohio State Medical Association will also meet. An informal organization dinner will be served on the evening of May 4, after which the visiting anesthetists will be entertained at a smoker by the local entertainment committee of the Academy of Medicine. Anesthetists, surgical and dental, as well as interested surgeons, research-workers and general practitioners who wish to participate in the proceedings are cordially invited to attend. Those desiring further information or dinner reservations may address Dr. F. H. McMechan, Secretary, 1044 Wesley Ave., Cincinnati, Ohio.

Post-Graduate Course in Infectious Diseases.—Through the cooperation of the Medical Board of the Willard Parker Hospital, the Bureau of Hospitals, and the Bureau of Laboratories, a series of courses of clinical lectures and demonstrations in contagious diseases have been arranged for practising physicians. Each course consists of eight lessons, of which six are devoted to clinical bedside instruction and two to practical laboratory work. The sections are limited to ten members and only practising physicians are admitted. There are no fees, but physicians entering a course are expected to attend regularly. The first course began on Tuesday, March 2. Instruction is given on Tuesdays, Wednesdays, Thursdays, and Fridays of two consecutive weeks.

Regents Revoke Medical License.—At a meeting of the New York Board of Regents, held March 4, formal action was taken revoking the medical license of Walter E. Colgrove, M. D., and annulling his registration.

A Proposed Amendment to the Massachusetts Medical Law.—The Massachusetts State Board of Registration in Medicine has requested the Legislature to amend the registration law so that hereafter all applicants for examination shall hold the degree of M.D. conferred by a legally chartered medical school. All but three States of the Union demand a degree in medicine as a prerequisite to examination, but Massachusetts allows any one to take her examination if of good moral character, 21 years of age, and willing to pay the fee of $20.

Vacancies for Volunteer Clinic Physicians.—There are at present a few vacancies for volunteer assistant attending physicians in the Tuberculosis Clinics of the Department of Health in the Boroughs of Brooklyn and Queens. No salary is attached to these positions. Those holding them, however, are usually selected to fill the salaried positions in the clinics, when vacancies arise. Physicians desiring these positions should communicate at once in writing to Dr. B. H. Waters, Chief of the Division of Tuberculosis, Bureau of Infectious Diseases, Department of Health, 139 Center street, New York City.

Dr. Frank S. Wells, who had completed fifty years in the practice of dentistry, was the guest of honor at a dinner at Truell Inn on March 10, given by the Plainfield Dental Society, at which he was presented with a diamond pin.

Dr. Richard Mills Pearce of the University of Pennsylvania, addressed the Buffalo Academy of Medicine on Wednesday evening, February 24, on "Experimental Studies of the Spleen in its Relation to Anemia, Hemolysis, and Hemolytic Jaundice."

Dr. Janet T. Howell, lecturer in physics at Bryn Mawr College, has been awarded the Sarah Berliner Fellowship for Women. This fellowship carries with it a gift of $1,000 to enable the recipient to engage in research work in physics, chemistry, or biology. She is the daughter of Dr. William Howell of Johns Hopkins University.

A Woman's Number.—The May issue of the *Medical Review of Reviews* is to be a woman's number, all the articles contributed being from the pens of women physicians.

Typhoid Fever in New York City.—Statistics for typhoid fever in this city during the fourth quarter of 1914 have recently been published by the Health Department. The case incidence for this quarter is 1.2 for each 10,000 of the population, as compared with 2.8 in the corresponding period of 1913. Despite the fact that immunization free of charge is offered by the Department of Health, only about 10 per cent. of the persons exposed to typhoid fever availed themselves of this offer.

Charitable Bequests.—By the will of the late Edward Smith Kelly of Philadelphia the sum of $2,500 is bequeathed to the Howard Hospital.

By the will of the late Dr. John L. Bromley of Philadelphia the sum of $1,000 is bequeathed to St. Timothy's Hospital and a like sum to the Episcopal Hospital.

be judged by its past to a great future, will be hamlicense of Walter E. Colgrove, M.D., and annulling

Medical Society Elections.—The New Britain (Conn.) Medical Association, at its annual meeting held on January 7, elected the following officers: *President,* Dr. Maurice W. Maloney; *Vice-President,* Dr. R. M. Griswold; *Secretary,* Dr. T. W. Fox; *Censors,* Drs. Strosser, Reeks, and Potts.

The Vernon Parish (La.) Medical Society, at its annual meeting in Leesville on December 26, elected the following officers: *President,* Dr. D. O. Willis; *Vice-President,* Dr. J. H. Wood; *Secretary-Treasurer,* Dr. M. R. McAlpin; *Delegate to the State Society,* Dr. J. H. Wood; *Alternate,* Dr. F. P. Jones.

The Erie County (Pa.) Medical Society, at a meeting held January 5, elected officers as follows: *President,* Dr. Wallace R. Hunter; *Vice-President,* Dr. A. H. Roth; *Secretary,* Dr. Scott D. Gleeten; *Treasurer,* Dr. Hugh M. Moorhead; *Recorder,* Dr. C. H. McCallum; *Librarian,* Dr. Fred E. Ross; *Censors,* Drs. George A. Reed, D. H. Strickland, O. M. Shreve, John J. Bell, and David N. Dennis.

The Knox County (Ky.) Medical Society, at its annual meeting in Barbourville on January 5, elected the following officers: *President,* Dr. G. H. Albright; *Vice-President,* Dr. William Burnside; *Secretary and Treasurer,* Dr. Charles L. Heath; *Delegates to the State Assoeiation,* Drs. J. W. Parper and S. C. Jones.

The Hartford (Conn.) Medical Society held its annual meeting on January 4, electing the following officers: *President,* Dr. Frederick T. Simp-

son; *Vice-President,* Dr. Joseph E. Root; *Secretary,* Dr. Arthur H. Griswold; *Assistant Secretary,* Dr. Amos T. Harrington; *Treasurer,* Dr. Philip D. Bunce; *Librarian,* Dr. Walter R. Steiner; *Board of Trustees,* Dr. Phineas H. Ingalls, for three years; *Executive Committee,* Dr. J. B. McCook, for three years; *Board of Censors,* Dr. Levi B. Cochran, for three years.

The Washington County (R. I.) Medical Society, at its quarterly meeting, held at Westerly on January 14, elected the following officers: *President,* Dr. H. B. Potter, Wakefield; *First Vice-President,* Dr. A. S. Briggs, Ashaway; *Second Vice-President,* Dr. F. C. Pagan, Westerly; *Secretary and Treasurer,* Dr. W. A. Hillard, Westerly; *Auditor,* Dr. R. B. Smith, Westerly.

The Medical Society of Northampton County, Pa., met at Easton on January 15 and elected the following officers: *President,* Dr. T. C. Zulick, Easton; *First Vice-President,* Dr. C. C. McCormick, Pen Argyl; *Second Vice-President,* Dr. C. F. Welden, Bethlehem; *Recording Secretary,* Dr. W. G. Gilbert, Easton; *Corresponding Secretary,* Dr. F. E. Ward, Easton; *Treasurer,* Dr. C. F. Stoffiet; *Reporter,* Dr. W. D. Chase, Bethlehem; *Censors,* Drs. W. D. Walker, Bethlehem; W. P. O. Thomason, Easton, and A. A. Seen, Bangor.

The Upper Mississippi Valley Medical Society, at a meeting held at Brainerd, Minn., on January 13, elected the following officers: *President,* Dr. Lowthian, of Akeley; *First Vice-President,* Dr. O. R. Sanborn, of Bermidji; *Second Vice-President,* Dr. Werner Hempstead, of Brainerd; *Third Vice-President,* Dr. F. H. Allen, of Staples; *Secretary,* Dr. F. A. Bennett; *Treasurer,* Dr. Paul Kenyon, of Wadena; *Censor,* Dr. J. A. Thabes, of Brainerd; *Delegates to State Medical Society,* Drs. G. W. Beach of the State sanatorium, and Paul Kenyon, of Wadena.

The Medical Society of the County of Jefferson, N. Y., at a meeting held January 14, elected the following officers: *President,* Dr. S. E. Douglass, of Adams; *Vice-President,* Dr. J. D. Olin; *Secretary,* Dr. C. E. Pierce; *Treasurer,* Dr. Paige Thornhill; *Delegate to the State Society,* Dr. C. N. Bibbins; *Delegate to the Fifth District Branch,* Dr. J. D. Olin.

Obituary Notes.—Dr. John Patrick McGowan of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1888, surgeon on the gunboat *Yankee* during the Spanish-American War, visiting physician to the New York Foundling Hospital, visiting surgeon to St. Bartholomew's Clinic, consulting surgeon to the French Hospital, and a member of the New York State and County Medical Societies, the American Urological Association, the Association of Military Surgeons of the United States, the American Dermatological Association, and the American Association of Genito-Urinary Surgeons, died at his home after a long illness on February 28, aged 49 years.

Dr. Joseph Palmer Watts of Wakefield, Mass., a graduate of the Harvard University Medical School in 1905, and a member of the Massachusetts Medical Society and the Middlesex District Medical Society, died at his home, from tuberculosis, after a long illness, on February 16, aged 31 years.

Dr. Charles Eugene Lack of Brooklyn, N. Y., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1895, assistant surgeon to the Norwegian and Methodist Episcopal Hospitals, surgeon to the Coney Island Hospital, and a member of the American Medical Association, the New York State and Kings County Medical Societies, the Brooklyn Surgical Society, the Brooklyn Pathological Society, the Long Island Medical Society, and the Associated Physicians of Long Island, died recently at his home, aged 43 years.

Dr. Lester C. Mitchell of Hamburg, N. Y., and formerly of Minneapolis, Minn., where he was for many years superintendent of the Minnesota College Hospital, a graduate of the New York University Medical College, New York, in 1867, and a member of the Minneapolis State Medical Association and the Hennepin County Medical Society, died at his home on February 13, aged 72 years.

Dr. Lefferson A. D. Allen died at Woodstown, N. J., on February 17 at the age of 75 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1867.

Dr. Thomas Biddle died at Philadelphia of pneumonia on February 19 at the age of 62 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1876.

Dr. William Orlando Griggs died at Philadelphia on February 21 at the age of 70 years. He was graduated from Jefferson Medical College in the class of 1866.

Dr. Walter Montgomery James died at Philadelphia on February 24 at the age of 69 years. He was graduated from the Homeopathic Medical College of Pennsylvania in the class of 1869. He was for many years editor of the Homeopathic Physicians' Journal. He was a member of the Germantown Homeopathic Club.

Dr. George H. Rhodes of Tobyhanna, Pa., died at Savannah, Ga., on February 26 at the age of 58 years. He was graduated from Jefferson Medical College in the class of 1879. He was a member of the Crawford County Medical Society, and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. Fred H. Klaer died in the University Hospital at Philadelphia on February 27 after a protracted illness, at the age of 36 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1904 and he was instructor in medicine in the University. He was also consulting physician to the Westchester Hospital. He was a member of the Philadelphia County Medical Society, and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association. He was a member of the Pathological Society of Philadelphia and for a number of years its Recorder.

Dr. Alfred Walter Maynard of New York, a graduate of the College of Physicians and Surgeons, New York, in 1872, and a member of the American Medical Association and the New York State and County Medical Societies, died at his home on March 1, aged 64 years.

Dr. James Peckham Campbell of New York, a graduate of the Syracuse Medical College, Eclectic, Rochester, N. Y., in 1854, died at his home on February 27, aged 81 years.

Dr. Hugh Lewis Sutherland of Benoit, Miss., a graduate of the Tulane University of Louisiana, School of Medicine, New Orleans, in 1873, formerly on the State Board of Health, and a member of the American Medical Association, the Mississippi State Medical Association, and the Clarksdale and Six Counties Medical Society, died at his home on February 20, aged 66 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR NOTES—EFFECT ON SOCIETIES—ROYAL MEDICAL BENEVOLENT FUND—"MENTIONED IN DISPATCHES"—GUNSHOT WOUNDS OF THE HEAD—OBITUARIES.

LONDON, Feb 26, 1915.

WE have organized a Professional Classes War Relief Council and the Lord Mayor presided last week over a distinguished meeting in its support. It is composed of representatives of a number of societies and funds devoted to the investigation and alleviation of distress caused by the war. Among persons of the professional class it is specially intended to assist the families of those members of the class who have enlisted in regard to the education and training for the juniors and the employment or emigration or even maternity necessities of the seniors.

The Royal Medical Benevolent Fund is represented on this new council by Sir John Tweedy and Dr. Samuel West, and medical applicants for help to the War Relief Council will probably be first of all referred to the fund. In reference to other professions some have no organization able to play a corresponding part and may also be poor, while others are able to support the average distress within them, and in fact do it and more, contributing to the necessities of the less fortunate associations. The theatrical profession is in this happy position, as Sir Herbert Tree and Sir George Alexander stated it could provide for all its benevolent purposes and was always found ready to contribute to the distress of outside professional needs.

The event of the last year of the Royal Medical Benevolent Fund was its incorporation under the Companies' Acts, the cost of which had been met to a considerable extent by the president's donation. The working expenses equal about 7 per cent. of the income. The fund distributed during the year £5,302 10s. 8d., being an increase of £182 5s. 8d. over the previous year's distribution. In addition to this the guild distributed £540 8s. 7d. In the Grant Department £2,881 4s. had been expended on 254 cases—more than the amount subscribed, which was only £2,481 3s. 1d. The total income of the Fund and Guild, including receipts from investments, was £7,480 15s. 1d. and there was a balance in hand of £1,012 15s. 3d.

The effect of the war on our medical societies is conspicuous. At the meetings many faces are missed and the officers have considerable difficulty in securing material for discussion. Some sections have felt constrained to postpone proceedings and a feeling seems general that probably the appointed program is so uncertain of fulfillment that it is hardly worth while to attend. On the other hand the war provides abundant subjects for discussion and the meetings give the opportunity of talking over the news, congratulating any member of the R. A. M. C. who may be present on their gallant and distinguished services in the fields of our confrères, as described by the F. M. Commander-in-Chief, Sir John French. The large number "mentioned in dispatches" is commented on by the newspapers as is the sadder list of those who have not survived. One of them, Lieutenant Martin Leake, has been awarded the Victorian Cross a second time, having won it the first time in South Africa (1902), since when he has been in private practice, but again sought a commission on the outbreak of the present war and has already gained a second Victorian Cross.

At the Medical Society of London an opportune discussion was arranged on "Gunshot Wounds of the Head." It was opened by Sir Victor Horsley, who thought wide as the subject is, it could be profitably considered as to the causes of death and how to prevent them. He said he made many experiments some twenty years ago which confirmed those of Kocher as to the so-called explosive effect of high velocity projectiles. To register the effect he employed modeling clay which has some resemblance to the texture of tissues but retains exactly its change of shape, as altered by the projectile, so it was only necessary to fill the cavities produced by bullets to get an exact record of the complete effect of the shot. This method showed him that the explosive effect of the bullet was directly proportional to (1) the sectional area of the bullet, (2) its velocity, (3) the amount of water present in the substance through which a bullet passes, (4) that the forces of disruption were at an angle to the axis of the flight of the bullet, which he had not been able to completely determine. He had however obtained by this method points not otherwise obtainable but of some importance as (*a*) wherein the course of the bullet is most mischief done, and (*b*) by what force? The casts show the answer to *a* to be—as soon as the bullet at its highest velocity is surrounded by the largest mass of wet tissue. In the animal additional conditions are concerned. In answer to *b* there were two movements of the bullet—its progression forward and its spin around a central axis given to it by the rifling.

Misconception has prevailed as regards the turning over of a bullet. Some have supposed a very pointed one might turn over and over round a transverse axis through the middle of its length, progressing like a wheel, but this is not so; it only turns over once and does not do that until nearly half its course is passed, that is, when the progressive velocity is greatly reduced and the advance is more sensitive to obstructions which will first affect the light tip, the momentum in that differing greatly from that in the base. Further when traveling at right angles its traverse of the tissues is reduced, but the spin due to the rifling continues to the end. The conclusion follows that the turning over has been unduly credited with the great destruction of tissue which is really due to the high velocity and rapid spin.

In the discussion that followed Sir D. Ferrier, Mr. Richard Warren, Mr. W. H. H. Jessop and Major Bathe Rawling joined and many interesting observations were contributed.

The London Insurance Drug Committee is informed by the medical sub-committee that there appears a deficit in the amount available for drugs and appliances, approximately about £53,000. The attention of the Insurance Commissioners is called to this condition of the fund.

The death is announced of Dr. Edward C. Seaton in his sixty-eighth year. He was lecturer on Public Health at St. Thomas' Hospital and had been examiner in the subject at Cambridge, Oxford and the two Royal Colleges. He had taken a prominent part in obtaining the introduction of the Notification of Infectious Diseases Act and done much

other work in connection with public health.

Deputy Surgeon General Arthur Rudge has died at the age of eighty-nine. He received his first commission in 1850. He retierd on half pay in 1875.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

ETHYLHYDROCUPREIN IN PNEUMOCOCCUS INFECTIONS —ITS VALUE IN ULCUS CORNEÆ SERPENS—MODE OF ADMINISTRATION IN PNEUMONIA—RÔLE OF WORMS AND PROTOZOA IN THE ETIOLOGY OF TUMORS—EXPOSITION ON THE CARE OF THE WOUNDED AND SICK IN THE ARMY AND NAVY.

BERLIN, January 15, 1915.

SINCE the war began the various Berlin medical societies have held their meetings in common. At the first of these Morgenroth discussed the subject of the chemotherapy of pneumococcus infection. As the result of his extensive investigations he has found that the most active agent against the pneumococcus is ethylhydrocuprein. In experimental pneumococcus infection in mice and guinea-pigs the effect of this agent is an extraordinary one. As regards pneumococcus infections in human beings, there is a unanimity of opinion among opthalmologists that the remedy is particularly effective in ulcus serpens corneæ. Results so far obtained in the treatment of pneumonia have permitted no decisive judgment as to the value of this agent. Properly used at the beginning of the attack, this drug seems to shorten the course and diminish the severity of the disease. Following doses of 0.5 gram three times a day no adverse effects have been observed. No lasting disturbance of the organ of hearing has been recorded. If the drug is given in conjunction with the pneumococcus serum of Neufeld and Händel the effectiveness of the latter is greatly increased. The technique of the employment of ethylhydrocuprein in cases of corneal ulcer is as follows: Instillations of a 1 per cent. solution are made into the conjunctival sac, or instillations of a 1 to 2 per cent. solution following direct application of a 2 per cent. solution to the ulcer. Inunctions of a 1 per cent. salve six times daily may also be used. The speaker advocated the use of even stronger concentrations of the drug and also continuing the treatment during the night. In this manner may be prevented the drug-fast condition of the pneumococci resulting from the long intervals. For twelve to twenty-four hours prior to operations on the eye instillations of this drug into the conjunctival sac frees the latter of pneumococci. In pneumonia ethylhydrocuprein should be used in acute cases only and never later than the third day of the disease. Under these circumstances the temperature falls by lysis usually before the fifth day. The general condition and the respiration are greatly improved. Animal experiments as well as clinical observations show that the pneumococcus toxins increase the susceptibility of the conjunctiva to quinine. For this reason adverse effects are the more rarely observed the earlier the treatment is instituted. In the treatment of pneumonia Morgenroth also continues the administration of the drug during the night in order to prevent a condition of drug-fastness of the pneumococci. In malaria ethylhydrocuprein is more powerful even than quinine, the daily dose being 1.5 grams.

In the discussion Leschke reported his experiences with this drug. Even though a favorable influence may be observed at the height of hepatization, the least results are to be expected if the drug is administered on the first or second day of the disease. With the improvement in the general condition and in the breathing, the difficulties of nursing are greatly relieved. The height and the duration of the fever are shortened. Similarly in pneumococcus angina and pneumococcus infection complicating influenza the results of treatment are quite favorable. In pneumococcus otitis insufflations of ethylhydrocuprein are indicated. That the action of this drug is specific for pneumococcus infections is indicated by the fact that it is powerless in all other types of infections.

The rôle of worms and protozoa in the etiology of tumors was the subject of a paper by Saul. The parasites are not to be regarded as the intermediary host of bacteria that excite tumor formation. The action is rather as follows: the metabolic products of the parasites provide the stimulus which causes a melting down of the tissues in the immediate environment, and a proliferation of the more remote tissues. This is the influence exerted by the coccidia in the biliary passages and by gall-insects in plants. A similar phenomenon is observed in normal physiology, in the implantation of the fertilized ovum in the mucosa of the uterus.

It may be said at the present time that the Germans are divided into two great groups. One of these is facing the enemy in mortal combat for the preservation of Germany. The other group is busily engaged in lightening the burdens of those who are fighting under the colors. In order to bring before the eyes of the public what is actually being done for the soldiers, there is being held in the halls of the Reichstag an exposition on the care of the wounded and sick in the army. In one group there is demonstrated the entire sanitary service of the forces in the field. In the first place there is shown the first-aid kit which every soldier has sewed into his coat. Then there are shown the cases of instruments used in the various military divisions, the *x*-ray wagon, the instrument equipment of the field-hospital, and models of hospital tents and barracks. In a large battle model 12 meters long showing an attack upon a city and fortress of the enemy, there is presented a demonstration of every phase of activity of the medical corps. There are seen the medical officers, amid the rain of bullets, lying on their stomachs and bandaging wounded; the medical corps are seen at work in the transportation of the wounded, and at the dressing stations, the field hospitals, and base hospitals. Models are shown of transport wagons for the wounded, hospital trains, etc. There is also a demonstration of the medical equipment of the navy with models of sections of warships in the Imperial navy. A full-sized reproduction of the dressing stations on a modern warship is exhibited. Situated in the lower part of the ship, these rooms with their operating table and other equipment are specially constructed to adapt them to the motion of the ship. Then there are the ship's hospital with its beds similarly adapted, and the drug room with the chemical and bacteriological laboratory. Of special interest is the demonstration of the methods of transporting the wounded on board ship. A sliding hammock suspended from a rail has proved to be most serviceable. A third section of the exposition deals with the care of the sick. There are shown pictures and cultures of the various bacteria, and illustrations of the preparation of sera, etc. There are tables showing the results of preventive inoculation. This section also

contains exhibits on tuberculosis, the use of the *x*-rays in the management of the wounded, and the modern technique in the nursing of the sick, including their clothing, nourishment, exercise, etc. Diagrams and models show the progress made in the care of those who have become crippled. The occupations which are open to cripples are also demonstrated. Thus it is shown how an individual who has lost both hands and both feet may not only be able to dress and feed himself, but may also perform the work of a farmer. Another section of the exposition deals with the work of voluntary nursing in the army, including the organization and activity of the Red Cross. Last but not least must be mentioned the representation of the history of the sanitary service in armies from ancient to modern times. Among the lectures which were delivered in connection with this exposition may be mentioned the following: "Our Daily Bread: a Wartime Consideration," by Rubner; "The Treatment of Wounds in War," by Bier; "Voluntary Nursing in War," by Kimmle; "The Prevention and Management of Disease During War," by Kirchner; and "The Historical Evolution of War Sanitary Science," by Halländer.

THE FIGHT AGAINST TUBERCULOSIS.

To the Editor of the Medical Record:

Sir:—In regard to an editorial article with the above title, published in your issue of February 27, I take the liberty of offering a few remarks. All are agreed that tuberculosis or consumption has materially diminished on the whole for a long time, as your reference to Hoffman's statistics demonstrates; but Dr. Sweeny raises the very practical point whether the expenditure which has been incurred by the present attempts to eradicate this disease is warranted by the decrease in its death-rate, and arrives at the altogether defensible conclusion that it is not justified. However, you incline to the opposite opinion, and state that the death-rate of this disease began to drop immediately after the discovery of the tubercle bacillus in 1882, by reason of the greater care which had been observed in avoiding contagion, and that the evident slackening in the decrease since 1895, you believe, is due to the inefficiency of the present prevention apparatus which has, so far, only been capable of thwarting the incidence of the disease among "the middle and upper" or the intelligent "walks of the social strata," while the "lower, or the submerged tenth, has not been reached."

Now, all things being considered, it seems most likely that if any decrease in the death-rate of this disease occurred in consequence of the activity of the prevention-crusade, this hardly took place in 1882 (for Hoffman's table shows that there was a decline of 7.35 per cent, in the period immediately preceding that year), but directly after the contagiousness of the disease became officially acknowledged, and after Health Boards took legal action in regard to its registration, disinfection, and segregation. The earliest move of this kind was taken by New York city in 1896, Boston in 1900, Philadelphia and Chicago in 1902, and in other cities later. Hence it is probable that about 1899 or 1900 is the time when the preventive-measures began to be felt, if at all.

Taking Hoffman's table as a guide, the death-rate in New York, Philadelphia, and Boston from 1882 to 1901 was 3.40 per mille, and from 1892-1901, 2.51 per mile, and from 1902-1911, 2.13 per mile, giving a decrease of 0.89 per mille, or 26.17 per cent. between the first and the middle base, and only 0.38 per mille, or 15.13 per cent. between the middle and the last base. The 26.17 per cent. represents the decrease when no, or very trifling, prevention efforts were made, while 15.13 per cent. gives the decrease when all the possible preventive efforts, aided by millions of money were invoked to annihilate this disease, and in spite of this its death-rate increased 11.04 per cent. over that of the immediately preceding period. To show that the preventive attempts of the day are practically *nil*, it is but necessary to point out that the decrease in the death-rate between 1838 and 1841, and 1842-1851, when not a thought was given or a hand lifted in favor of special prevention, was 13.92 per cent., or only 1.21 per cent. less than is shown in the above period between 1882-1901 and 1902-1911, during which time, as stated, the so-called prevention-movement was in its most active stage.

I believe it was Hoffman who first voiced the maxim that the lowering of the first fifty per cent. of the death-rate of this disease is a comparatively easy matter, because this is effected among the thinking and intellectual classes, but to reach the second fifty per cent., which largely relates to the ignorant and submerged strata, is a far different and much more difficult undertaking. On the surface it appears to be a self-contradictory conception. For, if consumption is caused by a specific germ, which is transmitted to the well from the sick through contagion or infection, it must be a specific infectious disease, differing in no wise from smallpox and similar diseases. Why should the intelligent be more readily relieved of this specific disease by a consumption-prevention apparatus, than the ignorant or the submerged? A specific germ is no respecter of persons, whether high or low, and cannot be conquered by an appeal to intelligence, ignorance, bigotry, filth, poverty, or to any object except to the germ itself. When smallpox, syphilis, typhoid fever, diphtheria, and other specific infectious diseases are to be exterminated all attention is given and concentrated against circumventing the virulency of the specific microbe which gives them life and activity, and on nothing else. No more or less can be done in the case of pulmonary tuberculosis or consumption if the prevailing doctrine concerning its causation is correct. And it is perfectly natural that any preventive movement that is capable of wiping out one-half of the extent of the disease in a certain time, is able to annihilate the remaining half with the same facility and in less time.

Thomas J. Mays, M. D.

Philadelphia, Penna.

The doctrine that cleanliness, proper nourishment, right living, and the observance of all the rules of hygiene are of no avail in strengthening the defences against infectious disease is a novel one.—[Ed.]

The Cultivation of Human Tumor Tissue in Vitro.—D. and J. G. Thomson conclude that the growth of human tumor tissue and normal human tissue can be obtained *in vitro* in a medium composed of fowl plasma to which extract of the human tissue or extract of chick embryo has been added. The growth of epithelial cells differs from that of connective tissue cells. The former grow out in the form of buds or in a solid, advancing mass, whereas the latter radiate out in long, branching lines.—*Royal Society of Medicine.*

3. A Study of the Efficiency of Mixed Toxins (Coley) in Inoperable Sarcoma. A Critical Analysis of 134 Microscopically Proven Cases. T. W. Harmer.
4. A Study of Disturbances of the Stomach. H. F. Hewes.

1. The Carnivorous and Herbivorous Types in Man.—J. Bryant mentions the following facts as established in comparative anatomy. Body form influences intestinal length, regardless of food habits. Intestinal length varies with the species regardless of food habits. In a given species intestinal length may vary 100 per cent. This variation depends chiefly upon the digestibility of the food. Offspring of one mother have at birth approximately the same intestinal length. In a given adult individual of one species body form and intestinal length are dependent chiefly upon heredity, the form or digestibility of the food presented during the growing period, and the general habits of life. Sex plays an almost negligible part in this regard. The carnivorous or herbivorous habit is not obligatory. Animals predisposed by their species to one or the other of these extremes of food habit, may within wide limits when forced by necessity reverse their normal manner of life, being thus as it were facultatively carnivorous or the reverse. For example, the polar bear may be forced to live upon kelp, and the cow may exist in comparative comfort upon fish. In the group of mammals, the carnivora are distinguished by a long thin body form, and a short simple type of intestine in which the small intestine is markedly longer than the colon. The herbivora, on the other hand, present a marked contrast; the body form is short and thick, and the intestine long and complex, with the small intestine perhaps barely equal in length to the colon. In man, the intestine is of intermediate character, nearer to the carnivora than to the herbivora, but here also one finds extremes of difference in intestinal length amounting as in the lower animals to at least 100 per cent. at a given age or height. The author presents a series of tables bringing out the contrasts between the two types as regards the biliary and cardiorenal systems, chemical phenomena, the ductless glands, the digestive apparatus, diet, the eye, habits and diseases, etc. Two general principles underlie these contrasts. The first is termed the law of contrasts, *i.e.* where one can prove a given point for one type, its opposite may be expected to prove true in the other type. The second general principle is, that in a broad way the herbivor would appear from a study of the tables as a positive and the carnivore as a negative organism. The carnivore in short may be regarded either as an inferior or as a very highly specialized organism, for in him the only systems developed or remaining present in excess, are those necessary to the perpetuation of the species: the central nervous system, and the reproductive system.

3. The Coley Toxins in Inoperable Sarcoma.—T. W. Harmer has made a study to determine, if possible, the type or types of cases in which this treatment offers an expectation of benefit. The study is based upon 134 microscopically proven cases. It is concluded that the mixed toxins of streptococcus and the *Bacillus prodigiosus* are of value in certain cases of inoperable sarcoma. The treatment of primary or recurrent inoperable sarcoma with mixed toxins must be intensive. The increment of the dose and the interval between injections require some experience. This method of treatment is distressing and is never certain. This analysis has been undertaken, therefore, in the hope of ascertaining the types of cases which offer reasonable expectation of benefit. The institution of this treatment is unjustifiable in cases in which operative measures of reasonable safety offer possible hope for removal. A frank statement of the nature and the severity of reactions, and the probability of benefit should be made to the patient or some responsible person before the treatment is undertaken. Seventy-three cases after most rigorous criticism have been regarded as apparent cures. The small round-cell type apparently offers the greatest expectation of benefit followed closely by the spindle-cell type (excluding fibrosarcoma). Only a relatively small number of mixed cell type have been benefited. The use of toxins in cases with multiple melanotic growths does not seem justifiable but their use in single melanotic growths is legitimate. Regarding the tissue of origin the greatest number of apparent cures have occurred in bone sarcomata (exclusive of giant-cell cases) over 18 per cent. of the total number of apparent cures, with an equal division of round cell and small cell types. Giant cell cases furnish about 15 per cent. of the total number of apparent cures. The records seem to justify preliminary trials of toxins in carefully chosen cases in which slowly growing tumors have ruptured more or less extensively into the soft parts rather than immediate amputation. With skilful judgment a few limbs have apparently been saved. If such treatment is practised, the patient should understand that amputation may ultimately be necessary, and it should not be long deferred in the advent of increased rapidity of growth, repeated hemorrhages, considerable absorption, or superimposed infection. A small group on account of anatomical situation, viz., extensive involvement of the vertebræ, defy surgical eradication. These should be submitted primarily to surgical attack followed immediately by toxin treatment. The records justify this practice. Primary inoperable round-cell sarcomata of the cervical glands compose about 10 per cent. of apparent cures. Sarcomata arising from fascia and muscle, which have been apparently cured, have been situated in the lower extremity, abdominal wall, and back. They compose about 16 per cent. of the total number of apparent cures. Nine of twelve are of spindle-cell type. In a small number of cases the toxins produce a striking relief of pain.

1. Spinal Anesthesia in Gynecology.—H. J. Boldt states that in the thousands of cases of spinal anesthesia in which novocaine has been used there has been recorded no fatality attributable directly or indirectly to the drug. In the author's experience the undesirable effects of the drug are limited to the more or less severe headaches which sometimes continue for several days, but which are relieved by the administration of the mixed bromides. An important consideration in spinal anesthesia is the preliminary narcosis by means of scopolamine and morphine freshly prepared. Spinal anesthesia is indicated in comparatively few cases: in patients in whom inhalation anesthesia is contraindicated

because of some organic defect or because of exceptional obesity. Another advantage of the method resides in the fact that one can dispense with one assistant.

4. **Epilepsy.**—L. Pierce Clark summarizes the main points of his thesis as follows: The epileptic is possessed of a particular type of constitutional makeup which antedates the occurrence of the first epileptic fit; this make-up is predominatingly infantile in the emotional sphere of development; the affective defect is due to infantile psychosexual immaturity; the latter is largely due to early libidinous fixations on the mother or father and also may possess secondary but lesser fixations in other stages of sexual evolution on its way to adult heterosexuality; the fit is essentially a libidinous outlet or striving of the unconscious forces, which, though widely variant, yet possess many of the characteristics of the dream language and motive; all the epileptic manifestations are in harmony with each other, flow out of the disease and are reciprocal and comparable as a whole. It would seem in future that the prognostic points in any given case of epilepsy should be based largely upon the degree of defect in infantilism, the rigidity of libidinous fixation, and the readiness with which the individual epileptic may be induced to assume a proper adaptation to adult emotional life. This latter problem is largely the main issue in all the psychoneuroses. The physical handicaps of defective metabolism, such as constipation, mucocolitis, and the so-called autointoxication, need also to be considered; the latter act in the essential epilepsies only as contributing and exciting factors in undervitalized individuals who do not arise from hardy family stock. The truth of this statement may be shown in that the majority of epileptics have come disorder of metabolism, but when the same has been overcome the epilepsy in the larger number of such individuals still endures.

5. **The Binet-Simon Tests in Psychoses of the Senium.**—L. Wender believes that the Binet-Simon scale may be of some use in the diagnosis of early cases of mental enfeeblement in the aged, and that even in the absence of those gross disorders of conduct which would justify commitment to a hospital a definite diagnosis can be made by means of these tests. Furthermore these tests will become progressively more fit for the diagnosis of mental defectiveness if the various changes indicated are adopted.

4. **Splenectomy in Primary Pernicious Anemia.**—W. W. Roblee states that: 1. Primary pernicious anemia is probably due to a toxin which may be of bacterial, chemical or parasitic origin, and in some cases there is an increase of the unsaturated fatty acids. The spleen seems to exercise an influence favorable to the elaboration of these substances. These toxins appear also to cause a hyperemia of the splenic pulp because of changes in the blood vessels, which cause the blood to be poured directly into the pulp. The presence of the spleen seems to cause a diminution in the amount of the total fats and cholesterins of the blood which are antihemolytic. For these theoretical reasons, and because of the numerous cases on record in which a cure has been obtained in Banti's disease, which is closely related to pernicious anemia, splenectomy appears to be indicated in these and the closely associated anemias. 2. Removal of the spleen either in sickness or in health does not affect the patient injuriously. The operative mortality is not high even in very weak patients. 3. A rapid and striking remission of all symptoms appears, the change in the blood picture coming quickly and quite certainly. It is too soon to know whether or not any patients will be permanently cured, but it is quite probable that a large percentage will succumb to the disease within a few months after operation. Other methods of treatment should be combined with splenectomy, as more than one factor is doubtless at work in these cases. It will prolong life, and in one's incomplete knowledge of the etiology of this disease and the certainty that death will come under every other known method of treatment, the author believes that these patients should be offered this additional chance of recovery. Some patients have been reported symptomatically well at the end of nine months, even though the blood was not entirely normal.

5. **Complement Fixation in Parasitic Skin Diseases.**—J. A. Kolmer and A. L. Strickler present the following summary of their experiments: 1. With a polyvalent antigen of *Microsporon audouini*, complement fixation was found to occur in 78 per cent. of persons suffering with ringworm of the scalp. 2. The serums of two cases of favus studied yielded positive reactions with an antigen of the achorion of Schönlein. 3. The degree of reaction in both ringworm and favus was observed to depend in general, first, on the severity of the infection, and second, on the duration of the infection. 4. A culture of the scales of tinea versicolor, regarded as a doubtful culture of *Microsporon furfur*, reacted weakly or irregularly with the serums of ringworm and favus patients, and negatively with the serum of a case of tinea versicolor. 5. The ringworm and favus antibodies (amboceptors) fixed complement best with their respective antigens, but with relatively large doses of serum this specificity was not observed, owing probably to a biological relationship of *Microsporon audouini* and *Achorion schönleinii*. 6. The antigens of the fungi did not fix complement with the serums of syphilitics and that of persons suffering from scabies, impetigo contagiosa, eczema, acne vulgaris, and other diseases.

6. **Clinical Features of the Wassermann Reaction.**—E. L. Keyes, Jr., finds that: 1. A negative Wassermann is not sufficient evidence of the cure or absence of syphilis. 2. A positive Wassermann, unsupported by clinical evidence, is not sufficient evidence of the presence of syphilis. 3. A positive Wasserman does not prohibit matrimony. 4. A fixed, positive Wassermann in the later years of the disease does not inevitably point to the prospect of grave lesions. 5. A negative Wassermann after salvarsan, in the first year of the disease, does not mean that the patient is cured, or that lesions will not reappear before the reaction again becomes positive. 6. The return of chancre, glands, eruption

and positive Wassermann reaction, a few months after control of the disease by salvarsan in its first few weeks, does not prove reinfection.

11. Nitrous-Oxide Gas in Obstetrics.—J. C. Webster states that about ten years ago he began to use nitrous oxide gas in certain complicated obstetric cases. It was noticed that the administration caused no ill-effect to mother or child, did not affect the strength of uterine contraction, or lead to postpartum inertia. On a number of occasions the gas was employed during the passage of the head through the vulva, and relieved the patient's sufferings without interfering with the progress of delivery. During the past year in the author's service at the Presbyterian Hospital, Chicago, nitrous oxide gas has been used in labor to abolish the pains caused by uterine contractions. The technique is simple. Usually the administration is begun when the patient complains of second stage pains, though it may also be used during the first stage. In the majority of cases, however, gas is not necessary during the greater portion of this period. It has been found best to use a small nasal inhaler, the mouth of the patient being uncovered. The gas-bag attached to the tank is kept under low pressure and, as the pain begins, the patient is instructed to breathe quietly, keeping her mouth closed. Ordinarily, light inhalation suffices to produce the analgesic effect. It is not necessary to cause asphyxiation or jactitation, which are due to the inhalation of large quantities of gas. Expulsive efforts on the part of the patient are not interfered with, to any appreciable extent. As soon as the uterine contraction begins to subside the inhaler is removed and the patient is again conscious. This procedure may be kept up for hours if necessary. A nurse or assistant may be instructed so as to carry out the administration satisfactorily. Pure nitrous oxide gas or gas with oxygen (3 per cent.) may be employed. The former is, perhaps, most universally applicable. It may be used in private houses as well as in hospitals, the necessary apparatus being small, compact and easily transported. The amount of gas varies according to the duration of painful contractions, and the cost is therefore a variable factor. In the Presbyterian Hospital the ordinary small gas-tanks have chiefly been used, the expense of administration being comparatively small. In hospitals where large tanks may be employed, the cost may be reduced about one-half. This method is recommended as the safest and simplest method of conducting painless labor. Its advantages are as follows: The apparatus is simple, easily transported, and may be used by any practitioner. Deep anesthesia is not necessary. There are no ill-effects to mother or child. The strength of uterine contractions is not diminished, no matter how long the administration of the nitrous oxide gas is continued. The administration is under control all the tme, and can be stopped at any moment. This is a very decided advantage which is not possessed by any method which necessitates placing a patient under the influence of drugs administered internally.

February 1, 1915.

The Potato as a Universal Aliment.—Richter states that a universal food substance is one which is necessary to the life of a community, is within the reach of the smallest purse and is palatable either *per se* or through various forms of cookery. The great monotony of the menu in the poorest strata of society undoubtedly leads to the use of alcohol. A universal foodstuff must of course be one which is readily obtainable, and therefore one which can be readily stored in sufficient quantities. It must be grown on home soil and in quantities so large that imports become unnecessary. Does the potato fill all these requirements? This tuber originated in South America and about 1560 it was introduced by way of Spain to Italy and Burgundy, reaching England in 1584, encountering strong opposition. It was first grown in Austria in 1686 and in Saxony 1705, and strong prejudices had to be overcome before it became an article of diet; and perhaps only famine was responsible for its free consumption. In France it was unknown before the Revolution. The prejudice was due in part to confusion of the tuber with the fruit, the latter being unfit for consumption. At present the German acreage exceeds that of every other country, 12.6 per cent. of arable land being given up to the potato or over five times the acreage of England. The tonnage of the potato crop has increased enormously in late years. An acre of potatoes contains more nutriment than an acre of vegetables or cereals. In addition to an enormous human consumption potatoes are used very largely for fodder, and for making spirits. The per capita consumption of potatoes of human beings is about 400 lbs. per annum, but the amount used for fodder exceeds considerably that used for human food, while half as much is used for distilling as for feeding the people. By cutting down the fodder or spirit production, or both, the public can benefit by large reserves of food. The potato is far from being an ideal food in itself, for it is almost fat free, and its protein content is small, although quite utilizable. The tuber loses nearly a fourth of its nutriment by peeling. To depend upon the potato for all the protein requirement an Irish day-laborer finds it necessary to eat about 13 pounds a day, and the same ration obtains among the peasants in parts of Silesia and Bavaria. However, under the more recent teachings concerning the sufficiency of low-protein diet such amounts may be far too large. In other words, from half to two-thirds the amount of potatoes mentioned above may furnish the protein requirement of subjects engaged in moderate activities, while at rest a much less amount will sustain life and even give a surplus of stored N. This laboratory find does not quite agree with clinical experience, however, for a potato diet is used to some extent successfully for the reduction of weight. When eaten as usual with butter loss of weight does not occur. Those who have used the potato diet in practice further state that if more than five pounds daily are consumed beyond an interval of several weeks symptoms of intestinal insufficiency develops. Those who are forced to eat these large amounts as sole aliment develop the well-known "potato belly" of the very poor man. From all that has been said, therefore, the potato will serve admirably as a leading constituent of diet. The theoretically advised eating of the skins is met by the objection that the latter cover up decayed regions and that only after peeling can these be detected and removed. Potato porridge, mashed potato, etc., form the best utilizable methods of preparation. Dried potatoes have never made good as a food product.

Latent Microbism in Surgery.—Melchior, who uses the term "quiescent infection" as equivalent to latent microbism, advises the surgeon to be careful in adjudging this or that surgical affection as cured lest delayed phlegmon, osteomyelitis, etc., appear because of latent microbism. Many phenomena which in the past have depended for explanation on the supposed presence of hypothetical "diatheses" and "constitutional predispositions" could be more simply accounted for by a demonstrable condition, such as latent germ life in which the germs become mobilized from one or another cause. Such a sequence obtains especially in wounds, in which adventitious germs are forced into the tissues but do

not at once manifest their activities. Extirpation of infected structures like tuberculous lymph-glands represents a condition parallel to the preceding. While the subject is in general a very old one, particular types are constantly coming to light, and the present war will develop others. The author refers especially to latent osteomyelitis from bullet wounds, appearing later as local lighting up or metastasis.

Münchener medizinische Wochenschrift.

February 2, 1915.

Peculiar Case of Anaphylaxis Towards Fly Stings.—Weber states that human beings often show a supersensitiveness toward animal substances, such as crabs, fish, and egg, which absorbed by the gastroenteric tract irritate the nervi vasorum of the skin and cause the formation of wheals, along with general phenomena which together make up the picture of urticara ab ingestis. When toxic substances are introduced parenterally into the body through the stings of fleas, diptera (bugs), certain hymenoptera (bees, etc.), coelenterata, etc., the individual reaction differ much among themselves not only in mankind but in animals as well. The frog is believed to be immune against hymenoptera (wasps) as far as swallowing them goes, but if fairly stung upon its tongue suffers greatly. The sting or "bite" of the tabanidæ (horseflies) causes the rapid formation of wheals, with formation of a circumscribed inflammatory exudate. The lesion is painful and itches intensely, and when it occupies the lip may be very large, becoming more so through rubbing; it may not disappear before two weeks. The course as a rule is benign, but at times the lesions behave like boils and may persist for weeks. In the case cited by the author the patient was a robust man in his forties. After a fly bite on the finger he was at once seized with vertigo, cyanosis, dyspnea, and collapse pulse. Later the face and eyes were injected; there was mental excitement and confusion, pupils were narrow and almost immobile. The wheal which formed locally occupied the site of the scar from a former horsefly bite.

Alcohol Criminality in Bavaria in 1913.—Rupprecht, a medical jurist, gives some data on this subject which should be of interest because of the great per capita consumption of strong beer, to say nothing of other alcoholic beverages, in this kingdom. The year 1912 showed a maximum over preceding years and led to a falling off during 1913. In 1912 12.47 per cent. of all those sentenced were drinkers, while in the following year the percentage agreed closely with that of 1911. These figures do not apply to the city of Munich, for here there was an increase in 1913 over 1912. For the entire kingdom the number of people sentenced for acts committed while drunk reached 8,639 in 1912, and fell to 7,637 in 1913 (7,695 in 1911). As is well known, alcoholic offences are characterized by their general rawness, grossness, etc. In about a half of all these crimes there was violence to the person. These appear most strikingly in rural districts, but there is also a notable distinction between the inhabitants of upper and lower Bavaria. Resistance to arrest is more in evidence in the cities—twice that in the rural districts. As to the personnel of the arrested, about one-half are day-laborers in the cities. In the rural districts farm laborers show a much smaller contingent of arrest. Adolescents (twelve to eighteen) contributed only about 2 per cent. of offenders, chiefly in rural districts. Considering the buoyancy and irresponsibility of youth and the number of dances, christenings, etc., which they frequent, this figure is not discouraging for the future, and leads to the conclusion that the city youth is more menaced by the alcohol peril.

Case of Balantidiosis Treated with Emetine.—Axter-Haberfeld, a practitioner of Brazil, relates the case of a woman, aged sixty, who had suffered for four years from diarrhea; she had up to twelve movements daily, with pus and occasionally much blood intermingled with water. She had become much emaciated and very weak. There was no fever nor any evidences of other affections. Microscopic examination of stools showed abundance of *Balanditium coli*, twelve or so to each field, and all in active motion. Treatment caused some improvement, but this did not progress beyond a certain point. Emetine was then substituted with most brilliant results. Even after three hypodermics of 0.039 the balantidium could no longer be found in the stools. The cure was permanent. Balantidiosis is not common in this locality.

Deutsche medizinische Wochenschrift.

January 14, 1915.

Nutrition Folder.—This number of the *Wochenschrift* contains a specimen of the folder which is being distributed throughout Germany from a central station in Berlin. After warning the public of the isolation of the Empire by its foes, the need of economizing in food is brought home by practical advice. The German is told that he should avoid meat for breakfast and supper, and also on certain days eat no meat at all. All meat scraps should be saved for soup stock, etc. The same prescription applies to fish. Fats are pronounced very expensive food stuffs (butter, cream). Economy should be practised also in the use of fat in cookery. All residues of fat should be saved for this purpose. Milk as well as sour milk and buttermilk should be used freely. Skim-milk is very cheap and may be utilized in various ways. Cheese made from milk is also cheap, and along with the latter may replace meat and eggs. Of cereals and breadstuffs, rye bread only is recommended and cereal porridges. All bread should be eaten stale and bread crumbs and fragments should be dried and kept for further use. Potatoes should be used freely, cooked in every possible way, when possible in their skins and eaten without peeling. At the hearty meal of the day vegetables should be eaten freely. Fruit cooked with sugar may acquire much food value, and jams and marmalades may replace butter. Water and milk are the best beverages. Alcoholic drinks should be used in moderation, but brandy should not be used, nor any excess of tea and coffee.

Disturbances of the Internal Secretion in Dysentery.—Peiser has long remarked certain peculiarities in the course of dysentery and after convalescence from the same. These could be connected with the operation of the internal secretions. The most striking, such as exophthalmus and lustrous eyes, suggested hyperthyroidism and as a matter of fact these were all the evidences of this state. The thymus as far as could be recognized was hypoplastic, while the thyroid in these cases was often found to be increased in size. Pancreatic insufficiency was recognized by several tests, including the results of installation of adrenalin (dilatation of pupils). More significant, however, as evidence of disturbed internal secretions, was the behavior of the organism towards carbohydrates. There was a marked tendency to intolerance and to glycosuria, which the author brought into relationship with the sympathetic (increased sympathicotonus). All these in association with other symptoms appeared to show that the balance between the thyroid-adrenal and parathyroid-pancreas groups was disturbed as if by the activity of the dysentery toxins. A practical hint is that belladonna should be used to lower the increased tonus of the sympathetic. The theoretical possibility was borne out by a trial. When ptyalism and gastrosuccorrhea are present opiates give good results.

Insurance Medicine.

The Betterment of American Mortality Statistics.—Perhaps it is but natural that only a comparatively small percentage of a nation's population even faintly senses the real importance of its vital statistics. Edward B. Phelps, editor of the *American Underwriter,* in writing upon this subject says that to most people mere figures of any magnitude are in the nature of hieroglyphics, and those recording births and deaths by hundreds of thousands probably make about as deep a dent in the average mind as would the photographic reproduction of a mass of newly-discovered cuneiform inscriptions of Nebuchadenezzar's time.

The medical profession of a country may be regarded as the architect of that country's vital statistics, every stone in the foundation of which is laid by some member of the medical profession, to wit, by the doctor who signed and filed this or that individual birth or death return. The statisticians who compile the vital statistics can only work with the building materials—certificates of births and deaths—which are placed in their hands by the doctors. If the metaphorical bricks of which the structure of vital statistics is to be builded are out of alignment through inaccuracy the structure is bound to suffer and be out of plumb, according to the degree of inaccuracy in the material supplied. Unfortunately the medical profession is anything but keenly alive to its responsibilities in this branch of its work. That fact is proven beyond all peradventure by the woefully defective registration of births in the vast majority of States in this country, and by the incomplete, inaccurate, and often positively misleading death returns, which certain medical investigations, or follow-up inquiries by statistical bureaus, have demonstrated.

The educational campaign in behalf of the general registration of birth returns, which has been conducted in the last few years by various public bodies and officials, under the expert leadership of Dr. Cressy L. Wilbur, Chief of the Division of Vital Statistics, Bureau of the Census, promises eventually to create a public sentiment which will demand the right kind of legislation necessary to enforce complete birth registration throughout the country. Physicians, medical bodies, and statistical bureaus of importance, are beginning to expose the inaccuracy of death returns, and this is bound to bring light into some of the dark corners of the American structure of vital statistics. This, in turn, will have a tonic effect upon the standards of the medical schools and the medical profession as a whole, and materially reduce the present percentage of careless, or incorrect, death returns.

Nearly a year ago Dr. Horst Oertel, then scientific director of the Russell Sage Institute of Pathology, and now pathologist of Guy's Hospital, London, published an article on the "Inaccuracy of Mortality Statistics," in which the large percentage of error in clinical and bedside diagnoses of causes of death as proven by subsequent autopsies—and, incidentally, the pitifully small percentage of autopsies in American hospitals—were emphatically demonstrated. Supplementing, as it did, and following on the lines of Dr. Richard C. Cabot's paper on "Diagnostic Pitfalls Identified During a Study of Three Thousand Autopsies," and the "Report on Post-Mortem Examinations in the United States," presented by the Public Health, Hospital and Budget Committee of the New York Academy of Medicine, Dr. Oertel's article commanded widespread attention. In an article entitled "An Experiment in the Compilation of Mortality Statistics," by Louis I. Dublin and Edwin W. Kopf, of the statistical bureau of the Metropolitan Life Insurance Company, is shown the interesting experience of that company in following up 5,118 more or less vague and unsatisfactory death returns and securing changed assignment of the causes of death in 2,827, or 55.2 per cent. of these cases.

The revelations of Dr. Cabot and Dr. Oertel are backed by actual post-mortem findings, and demonstrate errors in diagnosis. On the other hand, the showings of both the Census Bureau—which has issued a report on mortality statistics for the years 1911 and 1912—and the Metropolitan Life investigations rest solely on the admissions of the physicians who filed the original death certificates, and merely record their self-confessed errors of commission or omission in reporting the causes of death of the patients which they had attended. Presumably, in not a single instance of the corrected or revised death certificates, had the attending physician's statement of the cause of death been subjected to the test of any other physician's diagnosis of the case, let alone revised in the light of post-mortem investigation. So long as the greater includes the less, it follows that the percentage of error as checked up by these three different tests is materially larger than if only determined by second thought, and a reconsideration of the case by the one who made out the original certificate.

It would seem that inasmuch as the very foundations of a nation's vital statistics must be necessarily laid by the members of the medical profession, the medical institutions and societies which set the pace for the profession and determine its standards, might be expected to instill in the candidates for, and newcomers in, that profession some sort of realization of their responsibilities on these lines. Even did a post mortem follow every death, perfection in recording death certificates would be an impossibility, and not to be expected. But autopsies never have been and never will be popular with the community at large. However, a great improvement in existing conditions might be made by the mere exercise of a little more thoughtfulness and precision on the part of physicians who are called upon to fill out and file death certificates—that is to say, to the general cultivation of at least an approximate sense of medical responsibility in this detail of the reputable physician's work.

In order to bring about this desirable change, the wider the accurate exposure of the present inaccurate conditions the sooner the desirable change will come. The great business of life insurance has a peculiar interest in accurate statements of causes of death, if it is to intelligently determine which classes of risks it may, or may not, safely accept at standard rates.—*The American Underwriter,* March, 1914.

Insurance, Making Father Beneficiary, Right of Wife.—In a certificate of insurance in a fraternal benefit society, the father of the insured was designated as the beneficiary. Insured afterward married. It was held (Vanasek v. Western Bohemian Fraternal Asso. (49 L.R.A. (N.S.) 141) that the designation of the father as beneficiary was legal at the time it was made, and would be legal if made after the marriage of the insured, and that the marriage did not operate to make the designation void, or to substitute the wife as beneficiary.

Book Reviews.

TRANSACTIONS OF THE NATIONAL ASSOCIATION FOR THE STUDY OF PELLAGRA. Second Triennial Meeting at Columbia, South Carolina, October 3 and 4, 1912. Columbia, S. C.: The R. L. Bryan Company, 1914.

THE contents of these Transactions are divided into seven chapters, each of which, aside from the Introduction, comprises some special aspect of the pellagra problem, viz.: etiology, epidemiology and statistics; local incidence and diagnosis; laboratory developments; clinical features; treatment; and unclassified. The introduction consists of two general papers by Rupert Blue and J. W. Babcock, the latter dealing particularly with the general history of the disease in the United States. The fifty-two other papers practically cover every known aspect of the disease. To mention a few only of the more notable contributors we note the names of Lavinder; Sambon and Sandwith (both British); Gosio, Antoninin and others (representing Italy); Babès, the distinguished Roumanian pathologist; Ravogli the dermatologist, etc. However, the contributions of the native Americans are as a rule of a very high class. We see nothing from the pen of Searcy of Alabama who has studied the disease extensively. It cannot be truthfully said that the problem of pellagra seems anywhere near solution, despite the enormous labor represented by these Transactions.

LEHRBUCH DER MASSAGE von Dr. med. A. MÜLLER in M. Gladbach. Mit 341 zum Teil farbigen Abbildungen nach Originalzeichungen des Verfassers. Price, 18 Marks. Bonn: A. Marcus & E. Webers Verlag, 1915.

THIS work may truthfully be styled an atlas of massage. All of the necessary movements are illustrated by simple diagrammatic sketches which perhaps serve their purpose as well as could photography. Each outline sketch is accompanied by explanatory text which deals with the patient's position, the masseur's position and movements, and the anatomical relations of the parts involved.

The atlas so-called is preceded by over one hundred pages of texts, which deal chiefly with the physiological action of massage and the affections in which it is indicated. The operator is always spoken of as "the physician," not as "the masseur" and indeed in the preface the author insists that massage is but a specialty of medicine (and not a collateral profession, like nursing). The book is admirably suited for self-instruction, and even nurses and laymen with a little knowledge of German could soon learn the movements, although only in an empirical sense in the absence of exact anatomical knowledge.

TROPICAL DISEASES. A Manual of the Diseases of Warm Climates. By Sir PATRICK MANSON, G.C.M.G., M.D., LL.D. (Aberdeen); Fellow of the Royal College of Physicians, London; Fellow of the Royal Society; Hon. D.Sc., Oxon.; Foreign Associate of the Académie de Médecine, France; Honorary Member of the Société de Médecine de Gand; Hon. Associate of the Royal Academy of Medicine, Turin; Consulting Physician to the Seamen's Hospital Society; Lecturer in the London School of Tropical Medicine; late Medical Adviser to the Colonial Office and to the Crown Agents for the Colonies, etc., etc. With 12 color and 4 black-and-white plates and 239 figures in the text. Fifth edition. Revised throughout and enlarged. Price, $5.00 net. New York: William Wood & Company, 1914.

THE fourth edition of this work was published in 1907. The study of tropical medicine has advanced considerably since that time, so that a complete revision of the work has been rendered necessary. Some of the advances in tropical pathology which are described in this volume are the following: Kala-azar, particularly the infantile form, has been frequently observed in the countries bordering the Mediterranean; it is intimately associated in many instances with the dog; and peculiar forms of dermal leishmaniasis are to be found in South America. The transmission of *Trypanosoma gambiense* involves a necessary biological evolution in the *Glossina palpalis*. In Rhodesia there is a peculiarly virulent form of trypanosome transmitted by *Glossina morsitans*. The bite of a phlebotomus introduces into the human system an unknown germ causing a specific form of three-days' fever. Yaws is produced by a spirochete resembling that of syphilis. These represent but a few of the newer discoveries that are discussed in this volume. Among the therapeutic conquests in tropical medicine may be mentioned the prevention and treatment of berberi, the use of salvarsan in the treatment of yaws and relapsing fever; the treatment of trypanosomiasis by antimony, and the use of emetine in the treatment of amebiasis. Tropical medicine touches general medicine at many points, and the student of medicine can ill afford to ignore the diseases of the tropics, which diseases are carried by an expanding commerce into other climes, and which become important problems to health officers and government officials in the administration of colonies. The present volume in its 935 pages presents at most comprehensive survey of its subject-matter. It is written in a clear and scholarly style, and is profusely illustrated. The frontispiece is an excellent reproduction in color of a portrait of a case of pellagra in England. The section on malaria, which comprises 151 pages, is illustrated with many drawings and with two full-page colored plates, showing the life history of the malarial parasite. The work is particularly complete and well arranged.

DIE NEUEREN ARZNEIMITTEL, und die pharmakologischen Grundlagen ihrer Anwendung in der ärtzlichen Praxis. Von Dr. A. SKUTETZKY, k.u.k. Stabsarzt, Vorstand der Abteilung für innere Krankheiten am k.u.k. Garnisonsspitale, Privatdozent für innere Medizin; und Dr. E. STARKENSTEIN, Privatdozent für Pharmakologie u. Pharmakognosie an der deutschen Universität in Prag. Zweite, ganzlich umgearbeitete Auflage. Price, 12 marks. Berlin: Julius Springer, 1914.

THIS volume is a compact one, comprising 475 pages closely printed on thin paper, and is devoted to a description of the newer remedies and of their therapeutic applications. The first part of the book deals with the various diseases and points out the respective drugs indicated in their treatment. Then follow chapters in the artificial nutrient preparation; organotherapy; anesthetics, analgesics, and antipyretics; antiseptics; vaccine, serum, and chemotherapy, and toxicology.

QUAIN'S ELEMENTS OF ANATOMY. Eleventh Edition. Editors, Sir EDWARD ALBERT SCHAFER, LL.D., Sc.D., M.D., F.R.S., Professor of Physiology and Histology in the University of Edinburgh; JOHNSON SYMINGTON, M.D., F.R.S., Professor of Anatomy in the Queen's University of Belfast; THOMAS HASTIE BRYCE, M.A., M.D., Professor of Anatomy in the University of Glasgow. In four volumes. Vol. II, Part 2—Splanchnology. By J. SYMINGTON. With 439 illustrations. Price, $3.25 net. London and New York: Longmans, Green & Co., 1914.

QUAIN'S ANATOMY has been a standard work for some eighty years, and in its eleventh edition it has again been ably brought up to date. The present part contains the descriptive anatomy of the digestive system, respiratory system, urogenital system, ductless glands, and the peritoneum. The volume is of a convenient size which enables it to be handled with ease.

THE TONSILS, FAUCIAL, LINGUAL, AND PHARYNGEAL. With some acrount of the posterior and lateral pharyngeal nodules. By HARRY A. BARNES, M.D., Instructor in Laryngology, Harvard Medical School; Surgeon in the Department for Diseases of the Nose and Throat, Boston Dispensary; Assistant Laryngologist, Massachusetts General Hospital; Member New England Laryngological and Otological Society; Member American Laryngological, Rhinological, and Otological Society. Illustrated. Price, $3. St. Louis: C. V. Mosby Company, 1914.

IN this volume of 168 pages there is presented in most satisfying detail a description of the tonsils. It is based upon much original work on the normal and pathological histology of these organs, and deals with the clinical and surgical problems connected with them. The scope of this work is best indicated by its chapter headings, which are as follows: The general nature of lymphoid tissue; the development of the tonsil; the anatomy and histology of the tonsils; the function of the tonsils; the general pathology and bacteriology of the tonsils—their relation to systemic infections; diseases of the tonsils; diseases of the pharyngeal tonsil (adenoids); neoplasms of the tonsils; surgery of the tonsils; and complications and sequelæ of operations on the tonsils. The entire ground of this subject is well covered in its theoretical and practical aspects. Of particular value are the thirty-nine full-page illustrations including a series which portray the steps of the author's operation for enucleating the tonsils. One cannot but predict a wide sphere of usefulness for this volume.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 25, 1915.

THE PRESIDENT, DR. HOWARD LILIENTHAL, IN THE CHAIR.

Address of the Retiring President.—Dr. T. PASSMORE BERENS in a brief address to the Society said he was glad of the opportunity afforded him to say how deeply he appreciated the efforts of his friends to make his administration a success. The officers of the Society had worked conscientiously and with a spirit of great fairness. What had been accomplished would speak louder than words or praise from him. There was ahead of the Society serious work and their best efforts must be set forth to defeat the attacks of the chiropractics, the Christian Scientists, the neuropaths, and various irregular practitioners who were hammering at their defenses which they had strived for so many years to raise.

Inaugural Address of the President-Elect.—Dr. HOWARD LILIENTHAL made this address, in which he said, in part, that presumably his address was intended to form a record of good intentions. It might be better to wait until the last meeting of the presidential career, making the speech a valedictory instead of an inaugural, and an honest record of performances and failures instead of mere promises. To further the objects of the society, as expressed in the Constitution, "to regulate the practice of medicine and surgery in the County of New York and to aid in the enforcement of laws relating thereto" and also "to assist in the preservation of the public health" the president was dependent upon the efforts of the Board of Censors, the Committee on Legislation, the Committee on Public Health, and the Milk Commission. For the "diffusion of true science, particularly the knowledge of the healing art," the President depended entirely upon the members of the Society. Dr. Lilienthal said his predecessors had given much thought and great effort to carrying out the demands of the Constitution. As the years passed and the circumstances of their lives and civilization changed, new objects for their activities would come up. Questions would arise which could not be easily answered. Interpretations would have to be changed. But of one thing they might rest assured, that they must fight the same old enemies who would threaten in the same old ways and doubtless in many new ways. To keep their profession clean, to blockade any entrance into their territory through any port but that of *education* must be the aim not only of their Committee on Legislation, but of every single member of their Society who should feel it his sacred duty to enlighten and inform those who made their laws. There was no more serious menace to the welfare of medicine than this continual pounding at the door by those who sought the rights and privileges of legalized practice through unfair influence upon the uninformed. If this Society would truly diffuse knowledge concerning the preparation for the practice of the healing art it would do more to discourage quackery in all its forms than could be done in any other way. They might have confidence in the good intentions of their legislators and in the wisdom of their Governor, but information must come from the medical profession. Dr. Lilienthal said he could not let the occasion pass without expressing his deepest gratification for the work that was being carried on by the City Health Department against the patent medicine evil. To be rid once and for all of this monster would be a monument to the men who had achieved the victory. With regard to the Workmen's Compensation Law, we should remember that this was the first time that the medical profession had been considered in matters of this kind. We should not forget that the subject was still in the experimental stage. It seemed to the speaker that we should show ourselves friendly to this law and should be patient in regard to its development not being in haste to express either approval or disapproval of any of its provisions. As to membership, the Society was not an exclusive but an inclusive one. All eligible men in the County should be members. The membership on December 28, 1914, was 2,489, and there were at least 2,000 more who should be enrolled with them. Dr. Lilienthal urged every member to point out to his friends and acquaintances the great advantages of membership in the Society and to endeavor to bring in at least one new member. He pointed out the advantages of membership such as receiving the Medical Directory of New York, New Jersey, and Connecticut; the State Medical Journal, with its scientific papers, medical news, and official announcements; and, in addition, expert legal services in suits for civil malpractice. Membership in the County Society was also a help if one wished to remove from New York to practise in another State or if he wished to affiliate with the national body of the profession, the American Medical Association. In closing, Dr. Lilienthal reminded the members that acting as individuals their influence in the community would be small, but working together and with enthusiasm, the Medical Society of the County of New York must be a mighty force.

Stiff and Painful Shoulder, Its Varieties and Treatment.—Dr. WALTER M. BRICKNER presented this paper in which he outlined the various causes that he had found underlying a very common and much misunderstood condition, or set of conditions, variously regarded as due to rheumatism, brachial neuritis, or traumatism. After describing the most striking signs and symptoms of shoulder disability, the author stated that the various types so overlapped symptomatically that the general description might well be applied to most of them. Even in what seemed to him characteristic cases of one or another kind of shoulder disability he made it a rule to withhold his diagnosis until he saw the *x*-ray picture, after which he sometimes considerably modified his opinion. In the light of his experience he listed the causes of shoulder disability (excluding intraarticular lesions, gross fractures of the humerus, the acromion, the scapula and even the clavicle, dislocation of the humerus, subluxation of the acromion end of the clavicle, and unusual conditions such as cervical rib, etc.) as follows: (1) Subacromial bursitis. (2) Subacromial bursitis with injury to the supraspinatus or, occasionally, the infraspinatus tendon, and calcareous deposit. (3) Spinatus tendon injury with slight or perhaps no associated bursitis. (4) Fracture of the greater tuberosity of the humerus. (5) Subluxation (forward) of the humerus. (6) Spontaneously reduced dislocation; with which could be grouped disability following surgically reduced dislocation. (7) Sprain or tear of the capsule without dislocation. (8) Subcoracoid bursitis. (9) Biceps tendovaginitis. (10) Traumatic periostitis. (11) Developing syphilis, tuberculosis, and neoplasms of the head of the humerus. (12) True brachial neuritis. (13) Unclassified cases, most of which probably belonged to one or another of the above groups, but some of which perhaps remained to be accounted for otherwise. The first three of these causes were considered together. In typical cases the pain was greatest at the point of insertion of the deltoid, but was often complained of in the shoulder cap, the anterior aspect of the arm, in the forearm, or neck. In hyperacute cases the pain was severe, fairly continuous, and aggravated by the slightest movement. In chronic cases it was less definitely localized, usually less severe, and more intermittent. In hyperacute cases the patient held the arm rigid, resisting attempted abduction and internal rotation, and there would be found a tender point below the acromion, most often anteriorly. In typical chronic cases there was moderate or marked limitation of abduction and of rotation, especially internal rotation. The condition was by no means typical in its manifestations. As he had elsewhere pointed out there were fallacies in the generally accepted notions concerning subacromial bursitis. These fallacies were: that there was no diagnostic point of tenderness; that there was usually little or no swelling; that the shadow seen radiographically was never due to the thickening of the bursal walls, but always to a calcareous deposit; that this deposit was always beneath the bursa, in or on the supraspinatus or sometimes the intraspinatus tendon; that removal of the bursa was unnecessary and its complete excision was impossible except by mutilating dissection; that the condition did not arise from bacterial or toxic irritation, excluding the tuberculous form and the occasional metastatic suppurative condition. Subacromial bursitis was traumatic, the trauma sometimes being insignificant in nature, and again resulting from sudden or violent abduction of the arm. The author had found calcareous deposits at operation sixteen and seventeen days after trauma, and radiographically, ten, five, and even one day, after the occurrence of the injury. Whether early or chronic the deposit might be dry and gritty or semi-

fluid. In acute cases in which there was loss of function and the *x*-ray showed lime deposit, open operation afforded the promptest relief. In the less severe cases without evidence of tendon injury, abduction, preferably in bed by a simple method, which the author demonstrated, should be given a trial (see MEDICAL RECORD, Jan. 2, 1915). Fractures of the greater tuberosity of the humerus, when of considerable extent might be recognized by the pain, swelling, tenderness, and acchymosis; when slight in extent they presented about the same picture as subacromial bursitis, and could be diagnosed only by the *x*-ray; and here too the bone fragment might resemble a calcareous deposit. In this condition good results would follow fixation of the arm in moderate abduction for two or three weeks, interrupted at intervals for passive abduction, and followed by graduated movements to prevent stiffness. In speaking of subluxation of the shoulder, which had been refused recognition by some, Dr. Brickner said he had had three unmistakable cases, all cured by continuous abduction in bed for two weeks. They had the same type of pain as was observed in subacromial bursitis. There was distinct but slight prominence of the head of the humerus anteriorly and a corresponding depression posteriorly. As the arm was abducted to 90 degrees the deformity disappeared; in two cases with a distinct "snap". Disabilities due to spontaneous or deliberate reduction of dislocation and sprains and lesser tears of the capsule were best treated by abduction, passive movements and massage. Subcoracoid bursitis was not common. The most characteristic pain was in drawing the arm forward. Iodine, aspirin, and resting the arm in a sling effected a cure. Biceps tendovaginitis was manifested by tenderness in the bicepital groove, pain on strongly flexing the supinated forearm, and when the arm was swung back and forth. Treatment was by rest and anodynes. Traumatic periostitis could be recognized in the radiograph. Developing syphilis, tuberculosis, and new growths also presented characteristic radiographic pictures. Brachial neuritis was rare and was to be differentiated by tenderness of the nerves in the neck, the coracoid region and the arm; if of long standing there were also objective sensory, trophic, and motor disturbances. Shoulder disability of other types was frequently mistaken for neuritis especially when there was atrophy of the deltoid and spinati and radiation of the pain towards or into the hand. In various shoulder disabilities there was an associated circumscribed neuritis, or an extensive brachial neuralgia. Many of the unclassified cases responded well to the abduction treatment and probably belonged to the groups above described. Dr. Brickner illustrated his paper by lantern slides.

Dr. FRED H. ALBEE said that Dr. Brickner's paper was a very timely one. Many of these cases of deltoid bursitis were caused by our modern method of traveling especially where the passengers had to hang on to straps as they had to so often in the subway trains. Deltoid bursitis at the shoulder was not sufficiently recognized. A few years ago Dr. Albee looked over the text-books on joint diseases and found that practically nothing was said upon this subject, not even was the subject indexed. In only one chapter upon inflammation of the bursæ did he find subdeltoid bursitis mentioned. Subdeltoid bursitis had interested him very much since 1903, when he had an opportunity to study several operated cases with Dr. Codman of Boston, who was the first to point out the importance of subdeltoid bursitis and to give its pathology. Dr. Albee was particularly interested in the case of gumma which Dr. Brickner mentioned, and he had the opportunity to observe a case years ago with a beginning subdeltoid bursitis with syphilis as an etiological factor. This case puzzled many as it progressed to a full fledged gumma. It had been diagnosed as sarcoma by the *x*-ray; later as tuberculosis; later, after a pathological specimen had been taken, as osteitis fibrosa, but up to the time Dr. Albee first saw the patient the real diagnosis of gumma had not been made. The use of the *x*-ray was very important in making a diagnosis of these conditions about the shoulder as it was of other joints.

Dr. WILLIAM BENHAM SNOW said that he wished to relate his personal experience in cases of disability of the arm. Those that had been presented and beautifully illustrated upon the screen by Dr. Brickner represented a very small percentage and were found only in the advanced stages of bursitis. He was surprised that so many cases had come under the observation of one surgeon. Dr. Snow had found but few cases among upwards of three hundred cases that had come under his observation during the past fifteen years, in which the bursæ had become ossified. The majority of cases of arm disability were undoubtedly due to brachial neuritis and generally curable; but rarely so by rest or so called anti-rheumatic treatment. He had been able to cure nearly all of the cases that had come under his observation with the static current, which relieved the local congestion and cured the early cases in a few days, but often required persistent treatment for two or three months to cure the chronic cases. By placing a metal electrode over the scapula and extending it over the shoulder to the margin of the clavicle in front it was possible with the static wave current to exactly locate the place where the lesion was by the local pain produced; thus determining where the treatment should be applied. Dr. Snow stated that the failure to cure brachial neuritis and bursitis was oftentimes due to the fact that the location of the lesion was not definitely diagnosed by the attendant.

Dr. BRICKNER, closing the discussion, said he did not want his hearers to have the impression that subacromial bursitis, of all the varieties of shoulder disability which he had described, was the only one demanding attention. It was, however, a very common condition, much more common than some of the speakers seemed to appreciate. Dr. Brickner said he had exhibited but a few of his many lantern slides showing the calcareous deposit beneath the bursa.

The Inlay Bone Graft Versus Lane Plates in the Treatment of Fractures.—Dr. FRED H. ALBEE presented this communication in which he described his method of employing inlay grafts as a substitute for Lane plates in ununited and fresh fractures, especially comminuted fractures. He did not wish to be understood as recommending the inlay graft in all cases any more than the Lane plate. Open operation should be avoided whenever possible. Dr. Albee first presented the electro-motor tools which he had been using for this work. This equipment consisted of a small universal motor which could be used with any electrical current without adjustment. He had employed the outfit in 275 operations and it had never failed him. The automatic catch for holding the special attachments, such as lathe, twin saw, drill, etc., was similar to the catch used by dentists and was very easy of adjustment. Every part of the outfit which came near the operative field was capable of perfect sterilization. There was a small saw for deep cavities, such as laminectomies, the latest model of the author's twin saw, and a device by which the distance between the saws could be adjusted. This outfit was not absolutely necessary but was of great advantage as a large percentage of the work could be done more exactly and quickly, and with better results, especially in fractures. Dr. Albee showed a skiagraph in which two grafts were inserted to restore two-thirds of the tibial shaft which had been removed for sarcoma and demonstrated conclusively that the graft acted as a true graft in certain instances. In all bone grafts which were properly inserted, a certain varying number of the peripheral and central cells lived and proliferated and a varying part of the central portion of the graft acted as an osteo-conductive scaffold. In favorable subjects the entire graft might retain its viability, especially where the graft was inserted by the inlay method, which brought into close apposition each of the four elements or layers of the graft (periosteum, compact bone, endosteum, and marrow substance) to their corresponding elements in the recipient bone. The speaker emphasized the action of Wolff's law in its application to bone grafts. In a comparative way the bone graft was still more efficacious in gunshot or other fractures where there was comminution or loss of bone substance from infection, and consequent sequestration. In such cases the graft spanned the hiatus and its proliferation filled in the space, thus restoring the length and strength of the fractured bone. Wolff's law was operable in fragments as well as complete skeletal bones, and had an important bearing upon the plan of treatment and the progress of convalescence in a very large proportion of bone and joint work. In the 350 bone graft operations upon which this paper was based, in over 300 the graft was removed from the patient's own tibia and in none of these cases had there been any trouble with the tibia from which the bone was removed. The surgical problem which presented itself was not the securing of better fixation and a more close approximation of the fragment ends by bone removal and freshening, but the furnishing of an efficient internal splint and at the same time a bone-growing endosteo-conduc-

tive element which spanned these sclerosed areas and was at the same time closely and favorably contacted with the healthy vascular osteogenetic bone in each fragment beyond the eburnated area and distal to the point of fracture. The inlay bone graft fulfilled all these requirements and even more in that it acted as a strong stimulus to osteogenesis on the part of the host fragments themselves. The author's inlay technique varied somewhat according to the individual cases and their requirements. In small bones, such as those of the forearm, the inlay was best held in place by kangaroo tendon either placed in drill holes to the side of the groove or wrapped completely about the bone. In fresh fractures of the large bones where marrow cavity had not yet become filled with new formed bone and there was nothing to prevent the inlay from slipping into the marrow cavity, the graft and gutter beds were made wider at their periphery than at the marrow sides. With the fractured fragments held in proper alignment, the graft to be employed was usually removed from the fractured bone, generally the proximal fragment, and then slid distally into a groove one-half its length which had been prepared for it in the distal fragment. In the femor the sliding inlay should be five or six inches long. The author described his method of using the twin saws to cut the bone graft and also the technique of making the bone nails or spikes. In fractures of the long bones in which the difficulty of fixation was great, the inlay was held in place by the bone graft pegs or heavy kangaroo tendon, or both as seemed best. In severe comminuted fractures from gunshot wounds or other causes, where there was a space to be spanned and the length of the limb maintained by the inlay, it was best to tongue and groove the end of the graft and bone cortex of the gutter ends. The groove should be in the end of the graft, and the tongue in the gutter ends. The value of the graft in this type of cases could not be overestimated. An important point in the technique of bone grafting in its application to all types of fractures was the sufficient length of the transplant. In the case of the intramedullary graft this might afford a great deal of difficulty but with the inlay method it was accomplished with ease. A graft six inches in length could be inlaid as easily as one two inches. The intramedullary technique did not afford an ideal histological contact of host fragments, even when well executed, and this might explain some of the unsuccessful operations of this type. The two important advantages of the inlay method were: first, the ease with which sufficient contact with osteogenetic bone beyond the sclerosed area could be secured; and, second, the readiness with which this contact could be varied in accordance with the difficulties encountered. The more desperate the case and the more frequently it had been unsuccessfully operated upon, the longer must be the inlay transplant. A strong argument for the inlay technique was its universal applicability to all types of fractures of long bones, however near the joints they might be. An important mechanical feature of the inlay was that if it was inserted in proper relationship to the forces which were causing displacement, it became by its own inherent mechanics a most efficient fixation agent, irrespective of the means used to keep it in place. The author had repeatedly used the bone graft for spanning through tuberculous foci in Pott's disease of the spine and tuberculosis of the ankle and knee joints. The cortical bone graft would always withstand pure tuberculous infection, provided it had a satisfactory contact with healthy bone on each side of the infected foci; it would also resist attenuated pyogenic infection under similar conditions. This made it especially applicable to compound fractures in which infection was feared, or where mild infection had already occurred.

Dr. William Henry Luckett said that he agreed with all that Dr. Albee had said. His first bone graft case was one of the first performed in the city. It was for an ununited fracture of both the radius and ulna of one arm. Two unsuccessful operations had been performed, one for wiring and one for plating when the case came into his hands. He grafted a piece of bone from the tibia by attempting an inlay as a joiner mortises a piece. They obtained a fair result but the patient left the hospital too early, fell down, and refractured the arm and also broke the leg from which the graft had been removed. This and further experiences with ununited fractures had convinced him that every means known to medicine and surgery should be utilized before an open bone graft was contemplated. As an illustration, two years ago he tried an inlay along the lines laid down by Dr. Albee. The operation was completely successful as evidenced by clean primary union of the soft parts, and the *x*-ray showed the graft inlay in position with perfect apposition, but three months after there was absolutely no bony union. Thyroid extract, calcium lactate, Bier bandage, massage, etc., were all tried with negative result. A mechanical brace was made for the arm, but after wearing this for a month it caused an irritation and abrasion in the axilla which became the original point of infection for a violent general erysipelas that covered the patient's entire body and confined her to bed for nearly a month. When she got up she had firm bony union in the arm which had resisted all methods for nearly a year. In the opinion of the speaker the infection had caused some biochemical change or readjustment of the internal secretions that resulted in stimulation of an otherwise negative ostegenetic process. There had recently come into his hands a child with an ununited fracture of the tibia of two years standing. Two operations had been performed by well known and capable operators but there was absolutely no union; in fact, some disappearance of bone tissue at the site of the fracture had been noted. At one of these operations the tibia was also fractured and it evidently promptly united. It was a common occurrence where there were more than one fracture in the body to have one unite promptly and the other not, even though there was no interposition of soft part. In this case no reason could be found for the non-union. Some commotion was caused, however, in the laboratory by the request for a determination of the thyroid and calcium content of the child's blood. Last week, following the suggestion of Dr. Kauffer, the dental surgeon at the Harlem Hospital injected between the ends of the fractured bone a bone paste consisting of finely ground dehydrated bone and vaseline. This was thoroughly sterilized and injected with the aid of an old paraffin syringe. A report on the results would be made later. The speaker laid stress on the statement that in ununited fractures, not due to the interposition of muscle, fascia, etc., but to lack or absence of the osteogenetic process, wiring or plating was positively contraindicated. He did not believe that the final word had been reached in ununited fracturers, but up to the present Dr. Albee's method seemed to be the best.

Dr. Walter M. Brickner said he wished to discuss the physiological rather than the technical aspects of the presentation. He believed Albee's to be the most important contribution that had been made to the operative treatment of fractures. He was glad to note that the early enthusiasm over the Lane plate was dying out. Animal tissues were intolerant of foreign bodies. This was the general rule, and the fact that metal plates, applied to the bone, had sometimes remained *in situ* for several years, indicated only the exceptions to this rule. In many, if not most cases, the results were not so fortunate. But the fact that they might have to be removed was not only the only objection to the application to the bones of metal plates by metal screws. A year ago Brickner published an observation of two cases demonstrating clearly that metal plates and screws of themselves, independent of all other factors, could be a cause of non-union. These were two cases of fractured femur —one recent, plated by Dr. Lilienthal; the other an old, mal-united fracture plated by Dr. Brickner. In both cases there was primary union of all the soft parts but, in spite of every adjuvant treatment, no union of the bone. At subsequent operation in both cases the screws were found in place, but there was almost no evidence of new bone formation. Brickner removed the plates and screws and applied over the line of fracture an osteoperiosteal graft from the tibia. The graft was not inlayed; it was held in place merely by suturing the thigh muscles over it. In other words, it was applied purely as an osteogenetic, not as a splinting graft. Solid union proceeded promptly, and Roentgen-ray pictures taken at intervals showed no absorption of the graft but, on the contrary, its progressive fusion with the femur—an argument against the hypothesis that large bone grafts were merely osteoconductive. Since this experience Dr. Brickner had repeated this use of a non-splinting, osteogenetic bone graft for the cure of non-union, with entirely satisfactory result, and he commended its simplicity, as compared with inlaying, in those cases in which splinting by the graft was not needed. Concerning the importance of fitting like bone structure against like, referred to by Dr. Albee, Dr. Brickner thought that this might not be essential. In his cases of non-splinting grafting the medullary aspect

of the graft was laid on the outer (dense cortical) surface of the fractured bone, but osteogenesis proceeded from the entire length of the graft, as the Roentgen *x*-ray pictures showed.

Dr. WILLIAM WESLEY CARTER said that his experience with the transplantation of bone had been confined to the correction of nasal deformities where there was a deficiency in the bony framework of the nose. He used a section of the patient's own rib, which was split in its transverse diameter. The thin transplants thus formed were easily nourished, and besides the rib was unusually rich in minute nutrient foramina. He had used bone both with and without periosteum, and anchored the upper end under the periosteum over the nasofrontal process while the lower end was practically free in the soft tissues of the nose. Dr. Carter said that he had devised and used this method of transplanting bone five years ago and that his first results were published four years ago; his series of cases therefore was the oldest and the condition of the bone grafts in these patients as shown by the *x*-rays should indicate very clearly what happened to bone when it had been transplanted. Dr. Carter had found that when bone was asceptically transplanted it continued to live, grow, and take part in the local processes of repair. The graft became firmly united to the frontal bone and supported the nose, even in those cases where the nasal bones had been completely destroyed. Dr. Carter had found those transplants more vigorous where the periosteum had been preserved; he did not regard this membrane, however, as necessary to the life of the graft.

Dr. WILLIAM DARRACH said he wished to defend the use of the steel plate. He agreed with Dr. Albee that where union of the bone was delayed beyond a period of eight months, transplantation of bone was the preferable method. In such cases it was better to take the graft from some other bone. With regard to the use of inlaid bone in fresh fractures the field was small compared to the cases where the metal plates could be used because of the larger exposure required in doing the inlay work. The metal plate if inserted with good technique would stay in place. Personally he had used some 48 metal plates in a series of 210 operations for fractures. Of the 48 plates, 37 he knew to be *in situ* at the present time, after a period of at least six months. Two plates were removed because of infection. Three were removed because the fracture was a compound one. One case failed because of faulty technique. In two cases he cut down expecting to find infection, but none was found. Three cases had been lost track of, and twenty were uncertain. Eight plates removed out of 48 inserted and only two because of infection, should not condemn the use of metal plates.

General Faradisation (Bergonie) in the Treatment of Obesity and Other Pathological Conditions.—Dr. HEINRICH F. WOLF said that general faradization had been used extensively in the treatment of obesity. He corroborated the statement of Durig and Jebesny who claimed that they had been able to reduce some patients without change of diet, though the physiological experiments did not explain this fact; but in most cases a result could be obtained only when the diet was restricted. Greater than in the treatment of obesity was the general faradization in management of cases in which there were general debility, weakness of the heart, anemia, in short, such cases where strong muscular exercises were advisable, but could not be given on account of special conditions. It was of great value in the treatment of flabbiness of the abdominal wall, certain forms of constipation, and dysmenorrhea. It was obvious that in some of these conditions the general faradization acted by strengthening the muscles, but in others the improvement was due to the increase of the circulation, as was noted after muscular exercise. As far as the changes of the circulation were concerned it was known from physiological experiments that the artificially produced action of the muscles, had about the same effect as voluntary exercises. In cases of obesity, Bergonie treatment was recommended, in connection with restriction of diet. General faradization had no influence on the blood pressure and as a rule did not increase the pulse rate.

Dr. ALFRED M. HELLMAN said that it was certainly most refreshing to hear a paper read that did not abound in praise for the title. His hearers were indebted to Dr. Wolf for bringing this subject before them in so clear and so concise a manner. The speaker's experience with this treatment was limited to a short visit made to Dr. Nagelschmidt of Berlin last summer and the use of the apparatus in connection with his gynecological work, since his apparatus arrived from abroad over two months ago. He could not agree entirely with the paper that had been read. He feared Dr. Wolf was too pessimistic. His apparatus differed from that of Dr. Wolf's in two essentials. The chair was better made and distributed the current to a larger surface of the body, thereby being less painful and causing more muscles to work. The other difference was more important. To the motor was attached the Nagelschmidt apparatus, consisting of a series of fine copper brushes for interrupting and transforming the current so as to make it a smooth Leduc current. From the gynecologist's point of view the chair was useful in certain forms of amenorrhea, where it acted by improving the circulation, and in some cases by reducing weight. These cases were often complicated with constipation due to laziness of the bowels. Here the results were admirable. In dysmenorrhea due to local congestion and milder grades of retroposition this treatment seemed to work miracles. This was probably due to an improvement in the circulation and muscular tone. Retroversions with lax ligaments too were much helped by increasing the muscle tone by passing this current through the abdomen, pelvis, and back, and it was not unusual to find a uterus that was just resting on the rectum assume a position much more near the normal when this treatment was combined with proper exercises such as those in the knee-chest position. And finally the annoying lax abdomen following pregnancy with the wide diastasis of the recti and its frequent complicating constipation was as a rule promptly relieved and the condition cured. He was not sufficiently informed to speak of the value of the treatment in non-gynecological conditions such as muscular dystrophies, but he had heard it praised for this purpose. It was certainly not a cure-all for gynecological conditions but, used in properly selected cases, it was a great pain reliever and obviated the necessity of many an operation.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held December 21, 1914.

THE PRESIDENT, DR. THOMAS S. SOUTHWORTH, IN THE CHAIR.

The Theory of Workmen's Compensation.—Dr. FREDERIC W. LOUGHRAN, medical adviser of the State Insurance Fund Administered by the New York State Workmen's Compensation Commission, read this paper. He said that workmen's compensation legislation was based on the principle that industrial accidents, however caused, constitute a necessary part of the expenses of industrial production, which should be made a charge upon the industry, not the individual, and, as such, should be assessed in the first instance upon the employer, in the form of a premium for insurance, and by him passed on to the consumer in the form of an advance in price. The principle that the wreckage and wastage of the human factor in production should be made a charge upon the industry as an essential element in the cost of production had long been embodied in European legislation, but it was only within the last four years that it had been enacted into law in this country. The soundness of this principle was generally conceded by economists. These laws provided a method of indemnifying workers injured in the course of their employment which was more certain, speedy, economical, and equitable than the old employers' liability system. The latter was indeed most uncertain as a method of indemnifying the victims of industrial accidents, for it was a fact that on an average only one employee out of eight ever recovered anything in an action for damages brought against an employer. This system had also been very slow in operation, for, owing to legal delays, it often required months, and sometimes years, for an employee to secure his damages. Furthermore, it was most expensive, and on an average approximately only one-third of the amount so paid by employers ever reached the beneficiaries; the other two-thirds being eaten up by the toll taken out in transit for the various expenses involved. Finally, the system had been most unsatisfactory in its general effects upon industrial society, in which it made for strife and conflict by introducing an element of misunderstanding and controversy, ill-will, friction, and discord. The new law of workmen's compensation introduced a plan of

indemnifying injured workers which did away with these evils. Under it it was not necessary for the injured employee to go to court, nor was he required to prove fault on the part of the employer or his superintendent. The burden of proof had been shifted from the employee to the employer. The forty-two designated groups of hazardous employments included practically all occupations except domestic service, farm labor, and mercantile employments, and the act provided compensation according to a fixed scale, which entailed a disability of more than two weeks, except those occasioned by the wilful intention or the intoxication of the employee. This waiting period of two weeks was necessary to prevent a workman claiming a minor injury in order to obtain a vacation with pay. Having mentioned the rates of compensation for various kinds and durations of disability and in the event of death resulting from injuries, the speaker said that employers were not permitted to pay compensation directly to their employees, but were required to insure this liability, and for this purpose three options were offered: insurance in the State Fund, insurance in any stock or mutual company authorized to write workmen's compensation insurance in this State, and self-insurance under conditions provided by the Workmen's Compensation Commission. All claims for compensation had to be presented to the commission, and all payments to employees were made by it. As to the medical aspect of the workmen's compensation law, under the act the employer was obliged to furnish medical attendance as soon as he learned of the injury, and it followed that if the medical service were prompt and efficient, the time of disability was shortened and the danger of infection lessened, with a consequent absence of serious complications liable to result in a permanent disablement. During the time of treatment the attending physician had the opportunity of discovering any existing organic affection, and an effort could thus be made to correct any such condition present. The employer was benefited, since, as the period of disability was shortened, his trained working force was less disturbed. Another advantage to him was that he would learn to appreciate the necessity of having healthy workmen and of endeavoring to keep them so by means of proper hygienic and sanitary surroundings; for the healthy workman was usually efficient, and the efficient workman was less often injured. Furthermore, the community was benefited to the extent that the injured workman or his family would not become a charge upon the public charities. There was still another aspect to be considered. It had been alleged, with substantial proof, that in Europe workmen's compensation acts had been followed by successful attempts at malingering, it having been found more difficult year by year to get injured workmen cured of their disabilities. Physicians were accused of using such acts irregularly as a form of revenue, and workmen of exploiting their accidents. It did not follow, however, that all cases of simulation were wholly fraudulent, because there was nearly always ground for making the original claim. Fraudulent cases were not manifesting themselves in great numbers in this country, but there were already indications that before long they would be of sufficient importance to constitute a problem, and this problem could be solved only by the hearty co-operation of intelligent physicians. The object of this act was to return people to industry, and one of its effects was that people refused to go to work while they were in pain. Before it went into effect the uninsured workman whose muscles had become contracted and partially atrophied as the result of a broken leg was forced to go to work, and did go to work. Every day he found that the pain grew less and less, and it soon disappeared. On the other hand, the injured employee who received half or more of his weekly wage under a compensation act, and who for any reason was not ambitious, might, and sometimes did, refuse to return to work as long as there was any pain in the injured part. The longer such patients stayed away from work, the harder was it for them to go back, and unless prompt and stringent means were taken to force them to return to work, the atrophy present would grow permanent and the individual become a charge on the law up to the full period of total disability, and subsequently on public or private charity. Some workmen who were afraid of pain or were victims of bad advice refused to accept the medical service offered by insurance companies which was necessary to put them back on a working basis. As to the remuneration of the physician, the Industrial Commission of Massachusetts had reported that the average amount received for medical attendance was now from four to five times as much as it had been under the employers' liability insurance. It could not be too strongly emphasized that in the past, in from 50 to 75 per cent. of the cases, taken in the aggregate, no pay had been received for medical services rendered, while most of the cases paid for by the insurance carrier or the employer went to the contract surgeon; an immense amount of free work being done by the family physician and the hospital. In discussing the amount of the fee for medical services the fact should be borne in mind that, according to the law, the charges must be made on an industrial accident basis alone. Both England and Germany exhibited the effect of general contract surgery, as carried out on an enormous scale, and in view of the fact that the cost of medical services had increased out of proportion to the cost of compensation, it was well to consider that such a system might in the future prevail in this country. It was easy to conceive that with the progress of these laws, unless they were properly safeguarded, they might result in the practical enslavement of the medical profession to a bureaucracy created by legislative act. Industrial accident boards had foreseen the possibility of such laws, and this was the reason why such extreme care had been taken that the initial steps in planning procedures should be along lines approved by the profession generally. In criticising the inevitable mistakes of such boards physicians should not therefore forget this, and when things had worked out as planned the profession would be left free from these bureaucratic trammels and retain all the rights of which, in the progress of social laws the physicians in European countries had already been in large measure deprived. Under Section 13 of the New York law the medical profession was receiving more in fees here than in any other State. There was no limit to the amount to be paid for medical services for the first sixty days, and this was a longer period than elsewhere. While the fees for specific surgical operations might appear very inadequate, it was to be remembered that the patients as a rule belonged to a class of patients from whom formerly nothing was received.

Dr. Thomas Darlington, member of the State Workmen's Compensation Commission, said he believed the working out of the present law, although like other laws it involved some hardships, would prove beneficial to the physician. The State Insurance Fund, administered by the State Commission, one of the largest of the insurance concerns having to do with workmen's compensation, had up to the present time received in premiums something like $1,400,000. Of this amount, $400,000 was expected to go to physicians in the State, and this money was largely for services in cases in which, under ordinary circumstances, they probably would not have received anything. It would no doubt be better that there should be a fixed scale of fees, but the Commission had not made any fee bill. It was absolutely necessary, however, for some of the insurance companies to have such. Personally, he had thought that the physician should adjust the price of his services to the position in life of the patient, but the Commission had been disappointed at the attitude of many of the profession. There was one thing to which he would like to call special attention, namely the large percentage of the cases in which there were septic wounds. It seemed to him that such a condition of affairs was at the present day entirely unnecessary. Under its surgeon, Dr. Sherman, the Carnegie Steel Company had worked out a system for the care of the health of its employees. Six years ago not less than 500 out of every 1,000 accident cases, or 50 per cent., had been of septic character, but after three years of betterment work the cases of septicemia had been reduced to one-eighth of one per cent. By proper and prompt attention septic wounds became practically a thing of the past, and such a result showed what could be done in this direction. He did not mean to say that the fees offered under the workmen's compensation law were commensurate with the skill and experience of physicians, but we were confronted with a condition, not a theory. Much could be done through the education of the manufacturer. It should be thoroughly understood that every injury, however slight, must be taken care of by a physician; this was simply economy for the employer, as it saved his money in the end. The Carnegie Steel Company had appreciated this, and had freely paid out its money in building hospitals and maintaining reliable medical and surgical staffs. The reports handed in by physicians, to which reference had been made by Dr.

Loughran, were sometimes almost illegible and often open to criticism as regarded the diagnosis made. Physicians should correct such matters for themselves, and the blanks provided were so conveniently arranged that it was a simple and easy matter to fill them out satisfactorily. Having cited illustrative cases in which the attending physician's claims had and had not been allowed, the speaker said that the Commission had no less than 300 cases a day to dispose of, any one of which might perhaps formerly have occupied a whole day in court. It could not accomplish all this work unless it had the aid of the physicians, and as an encouragement to them it could be stated that the fees allowed in New York were higher than those in any other State. The present law was certainly not without its defects, and it might be that the medical profession would be able to bring about suitable amendments. Physicians should always take their part in public affairs, and should endeavor to educate the communities in which they lived.

Dr. Alexander Lambert said that before the workmen's compensation law had been enacted the question arose in the House of Delegates of the State Medical Society as to what should be done. A resolution was adopted calling for the appointment of a committee to consider what should be the action of the profession in the matter, and later the Council appointed a committee with power. In looking over what had been done in the States of Massachusetts, California, Ohio, and Michigan this committee found that a schedule of prices had been fixed upon which was comparatively satisfactory. We were dealing with persons whose yearly income was for the most part $600 or less, and had to consider what charges were right for such. It was found, in general, that the rate of wages varied very little in the State and country, and the fee bills in the different States to a great extent agreed. Of all accidents met with, three-fourths were small injuries. Under the New York law the physician's pay commenced at the very beginning of the patient's disability, while the workman himself did not begin to receive his compensation for two weeks. In the State outside of the city of New York and two or three other large cities the ordinary charges of physicians were from 50 cents to $1.50 for office visits, and from $1 to $2 for house visits. The charge in the fee bill of $2 for each house visit, and $1 for each office visit, was therefore a very fair and just one for such visits even under the ordinary circumstances of general practice, and much more so under the workmen's compensation law; particularly as three-fourths of all charges made by physicians would come under these items. In general practice, however, it was one thing to charge for professional services, and quite another to collect the money; while under the workmen's compensation law the returns were practically 100 per cent. Dr. Lambert then took up and answered some of the criticisms which had been received from physicians in the State, and in speaking of hospital work stated that in Syracuse Dr. F. H. Flaherty had succeeded in getting one of the wards of St. Joseph's Hospital set apart, so that any physician in the city could treat in it his patients who came under the workmen's compensation law. It could not be denied that the fees allowed for this kind of work, when compared with those generally received by the successful surgeon, were very small; but this was not the case when compared with the fees which could be expected from patients with incomes of $600.

Dr. Warren Coleman said that the subject of workmen's compensation was so broad that it was possible to discuss only a few of its phases. As he understood these laws, they were but part of a general movement of society for the conservation of the health of the workingman; yet they were economic, rather than philanthropic, in their purpose. The ultimate goal of the conservation movement obviously should be the prevention of industrial diseases and injuries, or, if not that, at least their reduction to a minimum. The New York State law, in common with most other such laws, provided for medical examination of workers only after injury had been inflicted or when the patient was suffering from evident disease. Yet many diseases and injuries could be prevented if medical examination were made a condition of employment. For example, an epileptic should not be permitted to become a structural ironworker; a man with a barely compensated heart should not engage in a laborious occupation. Detection of the earliest signs of chronic lead poisoning might be made the means of preventing permanent disability. A dusty trade never caused tuberculosis; it merely brought out a latent process. Early detection of the disease would save the health, if not the life, of the employee and protect the employer against loss. With such facts in mind it seemed incredible that at the recent national convention of the American Federation of Labor in Philadelphia organized labor should go on record as strongly opposed to the physical examination of workers except in trades having extraordinary health hazards, and that the Ohio State Federation of Labor should have recently passed a resolution calling for legislation which would make it a penal offense for an employer to require medical examination of a worker as a condition preceding employment. That medical examination could be made a cloak to cover abuses might be perfectly true, but in the speaker's opinion the abuse and not the demand for examination should be made the offense. He could but express the hope that future laws could be directed as much to the prevention of industrial diseases and injuries as to compensation after the damage had been inflicted.

Dr. Lorne McDonnell Ryan said that one of the great objections to the present law was the period of two weeks during which the workman had to wait for the beginning of his compensation; which he thought was entirely too long. He supposed that the object of this provision was to prevent malingering. It might be that some would take advantage of an earlier time for compensation, but, on the other hand, this two weeks' waiting was a great injustice to the men who really did deserve the money. Most workingmen had wages just sufficient to live upon, and every day, in his practical experience with the law, he saw hardships suffered by men of all nationalities thus deprived of their earnings. Frequently these were obliged to resort to public charity because they were scarcely able to sustain life in themselves and their families during that two weeks. Illustrating another defect in the law was the case of a physician of his acquaintance. This physician had been treating, and successfully, a fracture of the clavicle, but he was told that he would have to turn the patient over to another doctor, who was employed by a certain insurance company; which seemed an unnecessary hardship. Still another defect was that in filling out the slips, as required, it was a difficult matter to determine the time of disability. In one instance in which he had amputated a finger the man had gone to work on the following day; but in another patient an abrasion of the skin might necessitate rest for a fortnight. To a great extent length of disability depended upon the individuality of the patient. Some had less courage than others, and pain affected some more than others.

Dr. Edward Wallace Lee said that in the future contract service by physicians would be coming more and more into vogue, and he believed that this was an excellent thing. He himself had for eighteen years been contract surgeon to a great railroad corporation, and the company had done everything in its power to render the service prompt and thoroughly efficient.

Dr. Darlington said that so far, the accidents had amounted to over six hundred a day, and for the treatment of these the physicians of New York State had received much money which they otherwise could not have collected. There was really much less malingering than might have been expected. Sometimes, however, there was met with a psychological condition which prevented a man from returning to his work. As long as there was no incentive for him to do so, he was likely to remain idle, and it was particularly hard to get Italians and negroes to go back to work. The length of the disability of the patient was indeed a very difficult thing to determine. He, for one, was in favor of the physical examination not only of workmen, but of everybody else.

Dr. Loughran, in closing, referred to the difference between surgical and economic disability, and said that employers were beginning to realize the importance of finding out the exact physical condition of men who had suffered from accidents, and the cases were now generally seen by the surgeon on the day before the patient was to return to work. There could be no doubt that the contract system had come to stay, and it was one which was increasing every day. Preventive medicine was the keynote of the present time.

---

1. Prophylactic Use of Sensitized Vaccines in Puerperal Sepsis.—S. T. Champtaloup believes it would be well to use a stock sensitized polyvalent streptococcal vaccine as a prophylactic in the face of an epidemic of puerperal infection. Doses of 100,000,000 to 500,000,000 of this vaccine should be given at forty-eight hour intervals, ten to fourteen days before the expected confinement.

Books Received.

Therapeutic Hints.

For Trigeminal Neuralgia.—Lemoine and Gérard accredit Plicque with the following prescription:

℞ Tincture of aconite.
Tincture of colchicum.
Tincture of belladonna, āā, 3 grams.
M. Sig.: Twelve drops every 6 hours.

—"Formulaire Consultations Médicales et Chirurgicales."

Treatment of Insomnia Caused by Pain.—Huchard and Fiessinger recommend the following:

℞ Pyramidon.
Acetphenetidine, āā, 0.2 gram.
Quinine hydrobromate, 0.1 gram.

This is to be given in a cachet two or three times a day.

Treatment of Flatulence.—P. Cohnheim recommends, in addition to the use of dietetic and hygienic measures, the administration of the following:

℞ Menthol, 0.1 gram.
Extract of belladonna leaves, 0.01 gram.
M. ft. pil. Sig.: One pill, t.i.d.

In mild cases the following carminative mixture is sufficient:

℞ Valerian,
Peppermint,
Fennel,
Caraway, āā 25 grams.
M. Sig.: One tablespoonful to a cup of hot water, morning and evening.

Eight or ten drops of the tincture of belladonna may be taken with the above.

—"Diseases of the Digestive Canal."

The Treatment of Verminous Appendicitis.—Hager is said to recommend the use of the following emulsion in the treatment of appendicular colic in patients known to harbor intestinal worms:

℞ Thymol, 2 grams.
Olive oil, 4 grams.
Gum arabic, 2 grams.
Distilled water, 60 grams.

This is to be administered in three doses of one tablespoonful each at hourly intervals in the morning, on a fasting stomach. In the evening a brisk purge is given. The treatment is continued for three days.—*Journal de Médecine et de Chirurgie.*

A Modification of Baccelli's Method in Tetanus.—M. Le Fur has treated at one of the military hospitals in France since the outbreak of the present war 250 wounded among whom there were 7 cases of tetanus. The first four were treated according to the ordinary method with chloral, bromide of potassium, and morphine in large doses, and all died. The last three patients were treated according to Baccelli's method with injections of phenol, to which the author added camphor, likewise in large doses, and all three patients recovered. The method used was the injection once or twice daily for six to eight days of the following solution:

℞ Camphor, 0.4 gram.
Phenol, 0.4 gram.
Sterile olive oil, 10 grams.

—*Bulletins et Mémoires de la Société de Médecine de Paris.*

A Spray for Acute Pharyngitis.—D. Braden Kyle finds that the following usually gives relief:

℞ Camphor, gr. ij.
Menthol (crystal), gr. ij.
Sandalwood oil, gtt. iv.
Liquid paraffin, ℥ j.

—"Diseases of the Nose and Throat."

THE CLINICAL SIGNIFICANCE OF AURICULAR FIBRILLATION.*

BY HUBERT SCHOONMAKER, M.D.

CLIFTON SPRINGS, N. Y.

IN the last edition of Mackenzie on diseases of the heart, is this statement: "The term 'fibrillation' is applied to a curious condition of the muscle fibers of the heart, where the individual fibers in place of contracting in an orderly and simultaneous manner during systole, contract rapidly and independently of one another. The auricle when in a state of fibrillation presents an entirely different aspect from what it does during its normal action." Mackenzie then quotes Lewis as follows: "The walls of the auricle stand in the diastolic position; systole, either complete or partial, is never accomplished; the wall as a whole is stationary, but careful examination of the muscle reveals an extremely active condition; it appears to be alive with movement; rapid, minute, and constant twitchings or undulatory movements are observed in a multitude of small areas upon its surface."

The stimulus which excites the normal heart beat originates at a fixed point in the walls of the auricles near the mouth of the great veins, a point suggestively called the "pace maker." Unmolested, the pace maker originates ryhthmical contractions of the auricles, which in turn transmit stimuli to the ventricles through the bundle of His.

Now under certain pathological conditions involving in particular changes in the auricular walls, changes which are not yet well understood, the stimuli instead of originating ryhthmically from the pace maker, originates arrhythmically and independently from a multitude of hypersensitive points causing a multitude of minor contractions which pass in as many directions, each antagonizing all the rest and thus preventing harmonious contraction of the auricular muscle. The muscle fibers being dissociated, fibrillation only is possible.

In normal rhythm the "bundle" receives and transmits to the ventricle one stimulus to each heart cycle. In auricular fibrillation, however, the bundle is being constantly bombarded by multiple stimuli. Now and then one passes over and is followed by contraction of the ventricle. In the very nature of things, this state of the auricle must cause an arrhythmia in which there is no sequence whatever. Observe this in the radial tracings of the accompanying polygrams; observe too that the tracings cannot be spaced and that the top lines are wholly inharmonious, and that in the venus curve the "a" wave is lacking.

Tachycardia is an essential clinical feature of auricular fibrillation unless associated with heart block. Uncontrolled tachycardia leads inevitably to myocardial weakness and dilatation. Digitalis, in full doses, slows the heart by inducing partial heart block. In auricular fibrillation, in order that myocardial energy be not wasted, partial heart block is desired. Therefore, digitalis is of peculiar value in auricular fibrillation. Not so in the other arrhythmias. In paroxysmal tachycardia, there is no dissociation of auricle and ventricle. They contract in harmony either at the same rate or at a fixed rate, as two to one. Then, too, the paroxysms are of short duration; too short as a rule to permit of digitalis effect.

The tachycardia of Graves' disease, with acute symptoms, is due to a toxemia, and if dilatation has not taken place, is uncontrollable by digitalis. A dosage sufficient to slow the heart to anywhere near the normal would certainly do harm by adding another toxic element. Digitalis, however, is of use in Graves' disease when the myocardium begins to decompensate.

Arrhythmia with or without tachycardia and due to extra ventricular systoles or extra auricular systoles (premature contractions) is seldom controlled by digitalis except as tonic doses associated with exercise of the voluntary muscles do so by improving the myocardial tone. Extra systoles are best treated by physical and dietetic methods and seldom call for digitalis.

If what has been said concerning the effect of digitalis in the arrhythmias be true, it follows that differentiation is important. Especially is it important that we recognize auricular fibrillation.

The cardiac arrhythmias, according to the recent classification of Lewis, are seven in number, namely—sinus arrhythmia (the youthful type associated in particular with respiration), paroxysmal tachycardia, auricular flutter, extra ventricular systoles, extra auricular systoles, heart block, and auricular fibrillation.

If one understands certain basic principles, an electrocardiogram or polygram in a given case makes differentiation easy, but the instruments essential to these tracings are not commonly available. Touch, sight, and hearing, however, are always available and are sufficient to diagnose auricular fibrillation in 90 per cent. of all cases.

An arrhythmia in which there is no regularity, no sequence, with the heart rate above one hundred, being uninfluenced by treatment, together with the positive or ventricular venous pulse, as seen in the neck, is almost surely due to auricular fibrillation. This, I say, can be determined without the aid of graphic methods if one is careful to discern physical signs.

The prognosis in auricular fibrillation depends

*Read at the quarterly meeting of the Ontario Co. Medical Society, Canandaigua, N. Y., Jan. 12, 1915.

on the degree of myocardial efficiency. If the ventricular rate can be kept sufficiently low so that cardiac over-fatigue and dilatation is avoided, the functions of tonicity and contractility being active, the prognosis as to life and comfort is good.

a course of carbonated saline baths and massage.

In Mackenzie's clinic at the London Hospital the routine method of administering digitalis in auricular fibrillation is to give one dram of the tincture, divided into three or four doses every

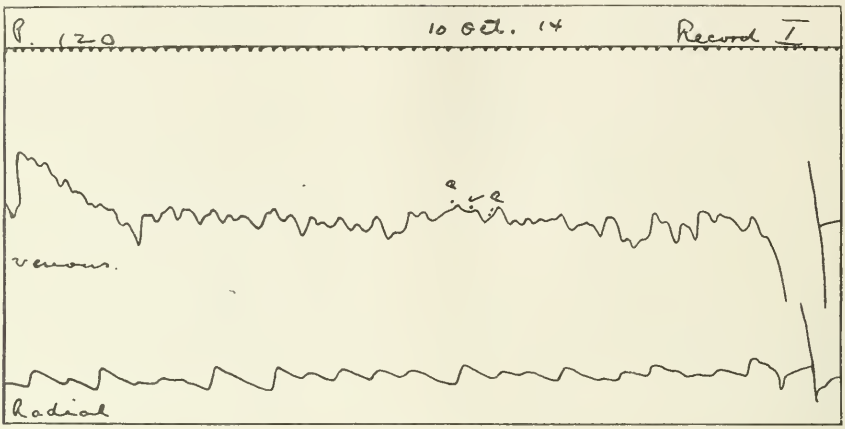

Chart I.

In auricular fibrillation in the senile heart of the sclerotic type, this is especially true. It is quite surprising what a degree of comfort and efficiency can be maintained in elderly persons with persistent irregular arrhythmia. In mitral stenosis, however, the prognosis is not good. When auricular fibrillation complicates mitral stenosis it does so because of late secondary changes in the auricular muscle and endocardium. The left ventricle already insufficient and, because of the stenosis, probably small, meets the burden of a new rhythm and the burden of tachycardia badly.

In the treatment, the essential point is how best to conserve myocardial energy. The chances are that any amount of treatment will have no effect on the rhythm but with slowing of the rate under digitalis, the number of forceful systoles should become greater and conversely the number of small and weak systoles less. This again

twenty-four hours. This dose is continued until nausea is induced. The drug is then omitted for one or two days and then resumed in sufficient doses to keep the heart rate below 80. Obviously the object of this method is to induce early the physiological effect of digitalis. In most cases of the rheumatic type, this is effective and safe, but in the arteriosclerotic group with or without kidney disease, the method is not without danger. Recently I had under daily observation for a period of six weeks, a man, aged 68. He was a case of cardiosclerosis with the usual changes in the arteries and kidneys. Upon admission there was auricular fibrillation, heart rate counted at the apex being 160. There was cyanosis and dyspnea both of moderate degree. The heart was dilated and there was stasis at the lung bases. He gave a history of slight infrequent precordial discomfort during the previous year, but at no time

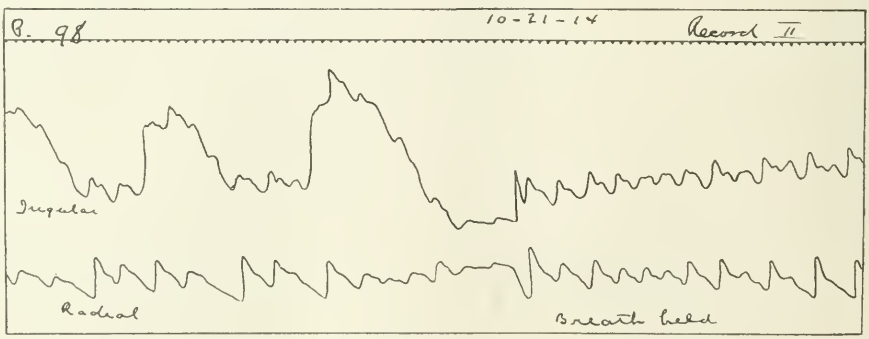

Chart II.

is well illustrated by the accompanying polygrams. Thus, while the rhythm continues irregular, the systolic output becomes sufficient to maintain a relatively normal circulation. In selected cases digitalis may profitably be supplemented by

had there been positive chest pain. The patient was sent to bed and given 10 minims of tincture of digitalis every four hours (40 minims in 24 hours) for two days. The lungs soon cleared and cyanosis disappeared. At the end of 48 hours the

patient complained of chest pain. This lasted six hours and was typical of angina. Recognizing the possibility of a plus digitalis effect and also the need of controlling the heart rate, the drug was omitted for two days and then given in five-drop doses three times a day, gradually increasing to ten drops three times a day, omitting every fourth day. This was continued until the time of patient's discharge—about five weeks. There was no return of pain.

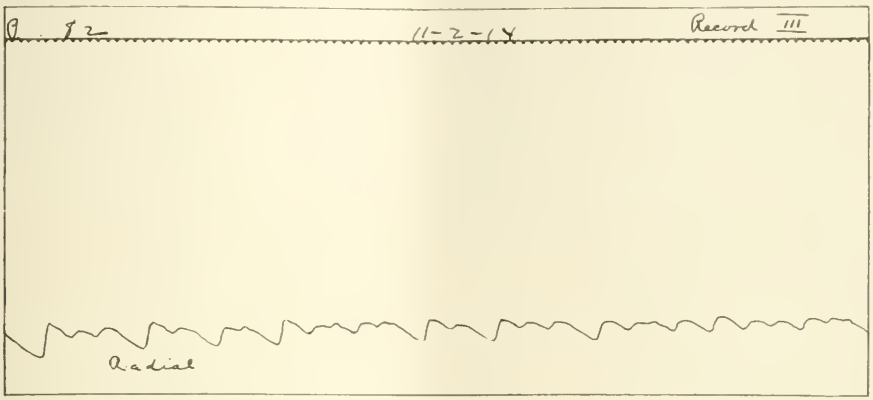

CHART III.

Conclusions.—Auricular fibrillation is the common cause of cardiac arrhythmia, characterized by complete irregularity.

Auricular fibrillation is of frequent occurrence, especially in mitral stenosis and in the senile heart.

Auricular fibrillation should be recognized without the aid of recording instruments.

Digitalis is of almost specific value in controlling the heart rate in auricular fibrillation and is of but little value in tachycardia or arrhythmia from other causes.

Angina pectoris may be induced by digitalis. Therefore in auricular fibrillation, especially in elderly people, it should be given cautiously, yet to effect.

CRITICAL REVIEW OF THE CONCEPTION OF SEXUALITY ASSUMED BY THE FREUDIAN SCHOOL.*

BY MEYER SOLOMON, M.D.,

CHICAGO.

ASSOCIATE IN NEUROLOGY, MAIMONIDES HOSPITAL.

MUCH, if not most, of the discussion centered about the Freudian movement has concerned itself with the conception of sexuality assumed by Freud and of rigorous psychic determinism, his theory of universally acting psychic repression, his theory of the significance of the resistance met with in the course of association of ideas and the significance of amnesia, his theory of the endopsychic censor, his conception of the unconscious, his employment of phantastic and highly complicated symbolism, the loose reasoning by analogy or the proof by *post hoc ergo propter hoc*, his explanation of the somatic symptoms of the psychoneuroses, his exaggeration of the rôle of sexuality in normal and abnormal life, and his many conclusions of a decidedly practical, medical, and therapeutic bearing, let alone the theoretical and purely scientific importance—although, I say, I find serious defects in so much of Freud's theories and conclusions, and have elsewhere[1] attempted to register very briefly certain objections to and criticisms of his psychology, I shall, in this paper, confine myself religiously to the question of sexuality.

My reasons for taking up for separate consideration the conception of sexuality assumed by Freud and his followers may be summarily stated as follows: In the first place, one cannot expect to discuss properly more than one or perhaps two of the many points of dispute in a single short paper. Secondly, the conception of sexuality has been made quite a central theme in Freudism and has been the chief source of opposition to the acceptance and spread of the Freudian theories and conclusions. Thirdly, there is quite a universal misunderstanding or lack of understanding, among the general profession, of the original conception of sexuality

*Perhaps it is necessary to mention in what sense the term "Freudian" is employed in this article. The Freudian movement or school, initiated by Freud himself, stands, in my opinion, for certain definite principles which may be summarized by stating that they consist of the theory of rigorous psychical determinism reaching far back to infancy and early childhood, and the conception of, or rather the general tendency toward the advocacy, at times by implication, of the individual intimacy of these experiences and the cause-to-effect relationship of early to later tendencies; the idea of the intimate significance of resistance to the flow of ideas in the association tests; the conception of psychical repression as underlying all mental processes not clearly conscious; the special sexual (incestuous, bisexual, Narcissistic, and polymorphous perverse sexual) theories with their extensive application (dreams, psychoneuroses, myths, therapeutic suggestions, etc., etc.), and the employment of highly complicated symbolism, besides the dynamic viewpoint and certain mental mechanisms which have been elaborated. Although there has recently been a deflection of a certain group of adherents, led by Jung, I believe that, for the purposes of this article, I am justified in including them among the Freudians, although Jung has substituted his theory of regression for Freud's theory of repression and has modified the Freudian concepts in some other ways, including the concept of sexuality, as described in this paper.

as outlined by Freud in his "Three Contributions to the Sexual Theory." Furthermore, the conception of sexuality as originally conceived by Freud and which, as such, was disseminated broadcast by his early followers, has undergone certain extensions and modifications at the hands of Freud, Putnam, and Jung in particular. Many of the followers of Freud are themselves not fully, if at all, aware of the modifications of the original conception of sexuality, the new standpoints assumed, and the significance of these newer ideas. Even as thus modified, I find that there are certain serious and important criticisms which must be leveled at the more modern conception of sexuality adopted by certain members of the Freudian school. It seems to me that it will be well worth while to review briefly the original and the more recent conceptions of sexuality and to endeavor to determine wherein Freud and his coworkers are correct and wherein they are in error in their theories.

I shall not deal in particular with the rôle assigned to sexuality in the genesis and evolution of dreams, the psychoneuroses, the psychoses, and the many fields of normal and abnormal human conduct. Nor shall I consider this question from the standpoint of its relation to the theory of psychic repression, the endopsychic censor, the unconscious, and the many other aspects of the Freudian psychology and the Freudian psychoanalysis.

I shall confine myself to a discussion of the conception of the sexual impulse or the sexual instinct —not its significance or rôle, but its definition, its delimitation, its origin, its composition, its evolution, and its goal.

I find, after several years' reading of Freudian literature that Freud, the foremost Freudians, the leaders of the movement both here and abroad, have not, in spite of their fearlessness in taking up the subject of sexuality and in boldly dissecting the sexual impulse, given us as complete and definite a conception or definition of that which they were discussing—the sexual impulse—as we would expect and demand from the positiveness and dogmatism of their conclusions. In fact, sexuality, or, rather, the sexual impulse, like the endopsychic censor and many other terms used by the Freudian school, has never been accurately defined by the members of the Freudian school. The leading Freudians have frequently found themselves in a position where it was difficult, in fact impossible, for them to tell us just what they meant by the sexual instinct or the sexual impulse. In their efforts at defense and in their attempts at explanations and elaborations of their conception, they have been compelled to indulge in hazy, mysterious expressions, in vague explanations, in ambiguous implications and mystical innuendoes, in certain general but indefinite statements which did not satisfy and did not really tell us just what they would classify as sexual. It was frequently only by hints and suggestive evasions, by innuendoes and implications, that one could obtain a fair idea of what the sexual impulse meant to the Freudian school.

More recently more definite standpoints have been taken. And it is for this reason that I feel that I can intelligently discuss the problem of sexuality in this paper, since I now have a better idea of what Freud and his adherents mean.

The writer here wishes to make note of the fact that in this paper he is not concerning himself with the views of Krafft-Ebing, Havelock Ellis, or the other investigators in the field of sexology, but he wishes it to be distinctly understood that he is confining his remarks to the conception of sexuality adopted by Freud and his followers.

Freud's Views in His "Three Contributions to the Sexual Theory."—With this end in view, let us, to begin with, very briefly review Freud's theory of sexuality as laid down in his "Three Contributions to the Sexual Theory."

Freud has laid special stress upon infantile sexuality—sexuality in the suckling and in the child. His conception of sexuality in the suckling may be stated as follows: The infant brings with it into the world the germ of sexuality. This sexuality is in the nature of autoerotism and has to do with what Freud has called the erogenous zones. The erogenous zones include the mucous membrane of the mouth, lips, and tongue, the anal zone, the neck of the bladder, and the genital zone. During the act of taking nourishment the infant derives a certain amount of enjoyment, pleasure, or gratification, which Freud classes as sexual pleasure, and which, subsequently, it endeavors to obtain by sucking, quite independent of the taking of food; thus, by the excitation of the mucous membrane of the mouth, lips, and tongue, acting as erogenous zones, there is obtained a certain sexual pleasure. The anal zone may afford sexually pleasurable sensations by the purposive withholding of feces and in other ways. The neck of the bladder may serve as an erogenous zone, as, for instance, by the production of enuresis, which, in the infant and child, when not due to epilepsy, means or is the substitute for pollution. In the genital zone activity in the form of masturbatory attempts may produce pleasurable feelings of a sexual nature. Various skin areas and sense organs may functionate as erogenous zones.

We thus see that, following Freud, in infancy sexuality is expressed by autoerotism and the dominance of the erogenous zones.

Let us now consider sexuality in childhood. The activity of these zones soon undergoes progressive suppression or a period of latency from the end of the second year to about the third to fifth year, about which time sexual activity reappears, frequently induced prematurely by seduction. Arising from autoerotic gratification, the sexual activity now takes on an object, accompanied by affects of an erotic nature, this activity being directed at first toward the parents and nurses, and then toward the sisters and brothers, without any special regard to the sex, but rather, in the beginning, with a preference for the same sex (homosexuality). We thus see that the child has incestuous, bisexual, better referred to as ambisexual (homosexuality and heterosexuality), and polymorphous perverse sexual tendencies. All of these are but the partial or component instincts or proximate elements, themselves not primary, which originally existed independently and functionated as such, were suppressed, and later go to form the sexual impulse or instinct. These components comprise the functioning of the erogenous zones, such as the skin, mucosa, and sense organ, excitation of which leads to what Freud believes to be sexual pleasure; exhibitionism, the peeping tendency, sadism and masochism, and others. Furthermore, the sexual goal is really present in double form—active and passive. Thus these tendencies, instincts, components, or elements, appear in contrasting pairs, one or the other (as, for instance, sadism, or masochism) predominating.

Sadism, according to Freud, is but the aggressive component of the sexual instinct acting independently and in exaggerated degree. Masochism is believed by Freud to be dependent, at least partially, upon sexual overvaluation and the painful irritation of the skin of the buttocks in spanking. Rhythmical mechanical movements of the body, such as occur in swinging, being tossed, rocking, etc., cause pleasurable sensations of a sexual nature. Muscular activity resulting from wrestling, conditions of fear and anxiety, and intellectual overwork may lead to sexual excitation.

We thus see that according to Freud the infant and the child have polymorphous perverse sexual tendencies or predispositions, and can be seduced or spontaneously direct themselves to all possible transgressions of the sexual impulse. Thus the sexual instinct is not a unit. It is a composite tendency or impulse made up of many different instincts, tendencies, components, trends, or elements, which we find set free again in the sexual perversions which Freud explains as being but fixations at or regressions to former tendencies or predispositions. These sexually perverse tendencies include the following conditions: Inversion (homosexuality), incestuous tendencies, and such perversions as fellatio, cunnilingus, pederasty, fetichism, the peeping tendency or voyeurism, exhibitionism, sadism, masochism, and others.

During the so-called sexual latency period (as Freud calls it), from the age of two to about three or five, there is partial or complete repression of the activity of the erogenous zones, with the erection of certain psychic dams or inhibitory mental forces, such as the feelings of shame and disgust, esthetic and moral standards, and, coincidentally, there occurs the splitting off from the sexual energies of a portion of the energy for other than sexual aims—the cultural and social aspirations or aims, this being of the greatest importance for the progress of our later and highest cultural developments. This latter process is termed by Freud "sublimation," or the socialization of the sexuality. This combined process continues more or less up to puberty.

We next come to the changes which take place at puberty. At this time there is a unification of the separate components of the sexual impulse with the subordination of the erogenous zones to the primacy of the genital zone. For this purpose the genital organs become developed and seminal secretion is formed. The sexual aim is now the end-pleasure, which, in the male, is obtained by ejaculation. With the finding of the genital zone there is the finding of an object, this consisting especially of the original infantile inclination toward the parents, nurses, sisters, and brothers, as described above. Furthermore, up to puberty the autoerotic activity of both sexes has been the same. The chief erogenous zone in the female child has been the clitoris, which is the homologue of the glans penis in the male. At puberty, in girls, there is a transference of the excitation of the clitoris to the vaginal entrance, which now becomes the sexually excitable zone.

The child's psychosexuality thus consists first of the autoerotic acts of the predominant sexual components, then the traces of love of an object, and the formation of the incestuous complex [especially that which is called by the Freudian school the root, or nuclear complex, named the mother, or (Edipus complex (in the case of the male), and the father, or Electra complex (in the case of the female)], with the affectionate and hostile emotions (love and hate) for the parents, brothers, and sisters, and other guardians or close companions. At first there is bisexuality, but finally homosexual tendencies disappear and heterosexuality alone remains.

But this is not all. What has been called by Freud "Narcissism" is said to be a necessary stage of development in the transition from autoerotism to the later love object. Narcissism is defined by the Freudians as love for one's own body or person. This Narcissism, or self-love, which to Freud and his followers is sexual, is the road to homosexuality in homosexuals and in all of us, since homosexuality differs from Narcissism only in the fact that in the former condition another individual or person with the same genitals as the developing individual has is substituted for himself as the means of getting away from himself. Thus the road to homosexuality is said always to pass over to Narcissism, or love for one's self, or mirror love.

Freud's Theory of the Sexual Development of Man.—According to Freud the sexual life of the individual may follow three possible courses of development: (1) The normal course consists of the union of the autoerotic trends present in the erogenous zones into the mature alloerotic instinct with reproduction as its goal—as previously outlined. (2) There may be an abnormal development of the sexual object or aim, with the persistence of the sexual activity of the erogenous zones, with the fixation at and the development of one or the other of the components or stages of the sexual impulse with the production of certain variations and perversions of the sexual impulse. (3) There develops a psychoneurosis, which is the negative of a sexual perversion, the symptoms of the psychoneuroses being but the expression of the sexuality of the patient and representing the incestuous, bisexual, and polymorphous perverse sexual trends of infancy and early childhood which have become repressed and unconscious in the course of development.

Fixation at or regression to one or the other of these stages in the sexual development (which, apparently, seems to comprise the entire development, if we would follow the Freudian school) of the child, is used to explain all normal and abnormal, physical and mental, conscious or unconscious conditions or tendencies or potentialities in mankind at any and every stage of his development.

The relationship of these ideas to the Freudian theories of psychical repression, the unconscious, amnesia, psychical determinism, the endopsychic censor, symbolism, and the various mental mechanisms, particularly transference, which have been made the groundwork of their psychology, and the application of these ideas to the sexual aberrations, and to the neurotic, psychoneurotic, and psychotic disorders, and to the host of other normal and abnormal tendencies and reactions of a physical and psychical nature, or both combined, I shall not discuss here.

The Meaning of Sexual as Given by Freud.—It is, however, plainly seen that Freud does not confine the term sexual to those processes which serve the function of reproduction, but that he would also include acts and tendencies whose main function is to give pleasure. We note that the infantile and childhood manifestations of sexuality are both mental and physical. The mental manifestations include attraction toward the opposite sex, curiosity

regarding sex topics, various phantasies and desires. The physical manifestations consist of the experiencing of and search for pleasurable sensations, the latter being at first very vaguely and diffusely distributed over the body, certain areas, called erogenous zones, being especially sensitive and active in this respect, with the changes and progress above mentioned.

In brief, it may be said that in his "Three Contributions to the Sexual Theory" Freud includes under sexuality incestuous, ambisexual, and polymorphous perverse sexual tendencies, and in addition certain, if not all, pleasurable bodily sensations. But in this work Freud had not shaped his theory as fully and clearly as could be desired. Naturally, as the theory was more elaborately evolved and became clearer and assumed a more definite form in Freud's mind, it was gradually extended and made more clean-cut and specific in its outlines. From indefinite, vague, mystical standpoints, or explanations, more and more definite standpoints were gradually assumed. Yet, in spite of Freud's many writings, he (and his school) has always found it most difficult to explain his conception of the sexual impulse. As a matter of fact, it is surprising that Freud's followers and others have not insisted upon a more definite elucidation of Freud's conception of sexuality than can be found even in the work above mentioned.

In the above lines we have thus very briefly reviewed the normal development of the sexual impulse in its various phases in human beings as conceived by Freud. This is explained more particularly in his conception of paranoia, of homosexuality, dreams, and the psychoneuroses.

Different Interpretations of Freud's Original Conception of Sexuality.—That Freud's outline of the evolution of the sexual impulse and of his conception of the sexual instinct was not as clear as it might have been, can be proved by citing the views of some of Freud's staunchest adherents. Maeder,[3] for example, uses sexual in the sense of love, as used in the declaration, "Hunger and love lead the world." This is certainly a vague enough statement. To me it is not an explanation at all.

Putnam[4] contends that sexual must be taken in the broadest possible sense, and that it must be conceived of as including all the affectionate and uplifting sentiments, since, as a matter of fact, it is his belief that our entire civilization consists of the transference and sublimation of the sex instinct.

There has been considerable discussion as to whether or not Freud includes all pleasurable feelings within the confines of sexuality, and if he does, whether he is justified in this attitude. Jones[5] agrees that pleasurable feelings should not be called sexual, and adds: "Certainly Freud, in his article on the two mental principles, categorically denied that the pleasure principle and sex were inherently connected, although he gave reasons to show how in the course of development the two usually become associated." I find, however, that most Freudians, including Freud himself, include all pleasurable activities under sexuality. Let us quote Freud[2] in this connection: "The analyses of neurotic disturbances of walking and of agoraphobia remove all doubt as to the sexual nature of the pleasure of motion. As everybody knows, modern cultural education utilizes sports to a great extent in order to turn away the youth from sexual activity; it would be more proper to say that it replaces sexual pleasure by motion pleasure, and forces the sexual activity back upon one of its autoerotic components." It is thus plainly seen that all motion and play are, according to Freud, fundamentally of a sexual significance, or nature. This could be extended by many examples taken from his writings and those of his followers. A few will suffice. Freud's conception of the pleasure in the acts of sucking, falling, swinging, floating, and the like, as being fundamentally of sexual origin and of a sexual nature, chimes in with the declaration just made. Brill[6] calls all dancing and motion pleasure sexual. Clark,[7] following Freud, groups tics as being of sexual significance. And one could extend the list by many more illustrations. An extension of this idea would naturally lead us to the conclusion to which the Freudian school finds itself forced, as will be shown later on in this paper.

It is worthy of mention that Putnam[4] finds himself compelled to class as sexual all pleasurable bodily sensations, all sense-cravings, all surgings, all massive feelings, all tumultuous heaving, all emotional yearning, all affection—in fact, all feeling, all affectivity, all physical or mental trends. Thus all conscious or unconscious, physical or psychical inclinations or activities, hence all motives and instincts, or the vital energy, must be sexual.

In a letter protesting against the general misunderstanding of the term "sexual," as used by Freud and his school, Wholey[9] explains that in the sense in which the sexual impulse is used by the Freudian school "it covers a broad and comprehensive field of experience and activity, whether bodily desires or mental longings. It embraces all desires, instincts, wishes, ambitions—like hunger, sex, acquisition, aspiration, the social sense, love, etc. This is a far cry from the narrow, vulgar conception of the term which seems to be understood by the men opposing the Freudian psychology."

Again Putnam,[10] in giving Freud's last word on his conception of the sexual impulse, quotes Freud, in free translation, as follows: "It is well known that psychoanalysts have been criticised by their medical colleagues for stretching the conception of the 'sexual' far beyond the limits ordinarily assigned to it. It is true that they have done this, but whether they are blameworthy for so doing is quite another question. The psychoanalytic conception of the sexual does transcend the limits of the popular conception in both directions, *i.e.* upward as well as downward; and the reasons for this widening of meaning become clear enough if one studies the sex life of man from the standpoint of its genesis. If, namely, the first stirrings or manifestations of the sexual instinct are taken as the point of departure, it seems justifiable to classify as belonging to and characteristic of the sex life, the entire series of tender emotions (zärtliche Gefühle) which come into being as outgrowths of these early impulses. This mode of classification is applicable even where, in the course of further development, the original goal of these impulses has ceased to exist as such, or has been exchanged for a wholly new one. Having learned to look at the matter in this way, we now like to use the term 'psychosexual' in preference to 'sexual,' in order to emphasize our belief that the higher mental constituents (seelischen Factor) of the sex life should be taken cognizance of and their significance fully recognized. In short, we now use the term 'sexuality' in the same broad sense in which the German word *lieben* is employed."

In another place Freud[11] expresses himself as believing that all such feelings and sentiments as sympathy, friendship, familiarity, and the like, are genetically bound up with sexuality and have been evolved by the softening or attenuation of the sexual goal from purely sexual longings.

This conception of Freud is analogous to that assumed by those followers who use the phrase "hunger and love," without, however, defining what they mean by these terms. Freud, on the other hand, uses the word "love" in a purely sexual sense, but includes under it all emotions and cravings, which also are conceived of as originally sexual, sublimation merely changing the goal or end by transfer of affect, which, also, would thus always be fundamentally of a sexual nature and origin. We thus see that all emotional surgings are of a sensual and sexual nature and origin, and, in the individual's life, had or still have sexuality as the ultimate and original goal.

It is to be noted, in particular, that the individual, with sexuality as his goal, is here being viewed from a purely psychological and individualistic standpoint. Emotional, originally and basically sexual, gratification is the will-o'-the-wisp which draws us on and on through the fascinating and mysterious, labyrinthine, ever-climbing, and ever-unsatisfied life of ours. The truly biological conception, with due regard for the racial or world history, which would include our phylogeny and ontogeny, is not given any real consideration.

To overcome this deficiency a biological and racial standpoint has been forced upon certain others (particularly Putnam) and the purely psychosexual and individualistic, present life history viewpoint is silently acknowledged to be too narrow, unscientific and theoretically and technically incorrect and not based on sound biological foundations. But, even here, it is found that, in spite of this acknowledgment in one place, an entirely opposite standpoint is assumed in another place, and, most important of all, the psychological, individualistic, and present life history standpoint is the one assumed, or rather definitely and practically exclusively carried out in the practical, clinical work and in the application of their psychological and sexual theories.

It is not such a far cry from Freud's conception, as outlined in the previous pages, to the yet more extended conception of his theory of the sexual impulse, whereby the vital energy of the universe is called libido, libido being referred to and used in the usual sexual connotation of the word. In his "Three Contributions to the Sexual Theory" Freud useed the word libido synonymously with the sexual impulse, or seexual instinct: "The sexual expression corresponding to hunger not being found colloquially, science finds the expression libido." Although Freud has never, so far as I know, definitely referred to the vital impulse as sexual, we find Ernest Jones[12] making the following statement: "The strongest opposition to Freud's views undoubtedly centers around the significance he attaches to the sexual instinct. It should be remembered, however, that Freud combats the narrow conception of this that generally prevails, and apprehends the expression in a much wider sense. From this point of view it will be seen that the importance he attaches to the instinct does not greatly differ from that of Schopenhauer's and Nietzsche's 'Wille zur Macht,' Bergson's 'élan vital,' Shaw's 'life force,' and the 'vital impulse' of so many writers, all of which are equivalent to what Freud terms the libido. He replaces these metaphysical or poetical phrases by a scientific and biological one—one that is also in harmony with the sound intention of the people, manifested, among other ways, through language, an example being the etymological unity of the words 'love' and 'life'."

In brief, this statement means that Freud's sexual impulse and libido mean the same thing as "Wille zum Dassein," "Wille zur Macht," "volonté de puissance," "élan vital," "poussée vitale," "life force," "vital energy," "vis a tergo," "universal energy," and similar terms. This is the racial and evolutionary viewpoint, and not the individualistic and psychological one. In this sense, self-preservation must be considered as a part of race-preservation, and cannot be separated from it. It is thus an offshoot of the race-preservative (sex-gratificative) tendency or impulse. Evolutionarily considered, this may or may not be found basically true, as mentioned later on in this paper, since the individual viewpoint or interpretation plays quite a rôle. One could, nevertheless, as stated below, give not a little proof in support of the proposition that race preservation cannot be considered, in and for itself, as the one and only exclusive, predominant, and original, and final goal of all the activities in the universe.

Finally we come to the more recent statement of Jung,[13] who, of all the Freudian school, seems to take the most rational standpoint—although he also is in error in certain important particulars.

Jung's Modification of Freud's Views.—Jung's views seem to require a more extended exposition, since it is evidence of a schism in the Freudian camp, and the adoption of a broader and more rational view of life and of man in particular. Jung's conception of sexuality is a biological one, in which the biological function of race-preservation or reproduction is linked with the ordinary conception of sexuality (as a physical sense and function). He himself shows some of the errors of Freud and his followers—errors which will be glaringly patent to all of us who have followed the exposition of the development of the Freudian theory of the sexual impulse as outlined above. And yet, as will be apparent to those who read the following lines, Jung has still permitted himself to be sidetracked by the Freudian theories and speculation.

Jung is willing to agree that the obtaining of pleasure is by no means identical with sexuality. His own argument is that "if we are to regard the striving for pleasure as something sexual, we might as well say paradoxically that hunger is a sexual striving, for this instinct seeks pleasure by satisfaction." But he adds, "if this were true, we would have to give our opponents permission to apply the terminology of hunger to sexuality." He admits that the emotion or pleasure which accompanies suckling, although not necessary for nutrition or growth (in the physical sense), is a state of tension or gratification which is not a sexual process, although analogous to the mechanism of the sexual act. This emotional mechanism is found both in nutrition and in the sexual function. It can no more be classified as sexual than can the sexual act be classified as a function of nutrition. Both acts or processes are accompanied by a certain feeling. We must differentiate between the process or activity and the content or feeling. Although granting that the infant knows nothing of sexuality,

still, when we come to the habit of sucking the finger and other habits, Jung believes that they are justifiably classed as sexual since the fact of correlation between masturbation and these childish habits producing a physical satisfaction from the child's own body (autoerotism) leads us so to believe.

Jung's method of argument is as follows: Sucking occurs in the function of nutrition, but its rhythmical activity, with the pleasure and satisfaction as a goal in and for itself, apart from obtaining nourishment, has a different significance, and is a characteristic present in other functions which have their final goal in sexuality. The hand (finger) may be used as an accessory organ—as in finger or thumb sucking. This rhythmical activity, with the consequent pleasure and satisfaction, may cease in the oral zone and be obtained in other places—as a rule first in the other openings of the body, then the skin in general and certain places of predilection upon it (rubbing, piercing, tugging, etc., on various parts with a certain rhythm and resulting pleasure); finally the sexual zone is reached with its onanistic attempts. This Jung refers to as the "march" of the libido, from the oral zone to other stations. This march of the libido occurs in what Jung pleases to call the "presexual" stage, and is characterized by gradual movement of the libido away from the sphere of function of nutrition towards the sexual function. Thus these activities of what Jung calls the "presexual" stage are not sexual but gradually give up their nutritional character and acquire sex characters. Furthermore, the polymorphous tendencies and activities of the libido in infancy constitute but a gradual movement of the libido away from the sphere of nutrition towards the sexual function.

Concerning the infantile sexual perversity made so much of by Freud, Jung asserts that the normal child has not perversions of the sexual impulse, but that these activities are the normal stages of normal sexual development. When, however, the early infantile tendencies are not given up when they should be there results an infantile, imperfect developing condition of sexuality, and then only do we have a sexual perversion—which is a disorder of fully developed sexuality and not a precursor of sexuality. In the perversions we have a retardation at or regression to that stage or process from which the libido has freed itself from the manifestations of the presexual stage. Jung thus makes a plea to give up the use of the term perversity in respect to the infantile polymorphous sexuality.

Jung now also takes issue with Freud with respect to the use of the term libido. He confesses that Freud used libido for the sexual impulse, so that the libido sexualis is made the bearer of the energic conception of the psychical life force. The sexual definition of libido must, he affirms, be abandoned, and in its place he would posit a more biological, dynamic, energic, genetic theory of the libido, whereby the sexual components are but energic manifestations of libido, the latter term being used in a new sense, namely, as referring to "that energy which manifests itself by vital processes, which is subjectively perceived as aspiration, longing and striving." In this way libido becomes the primitive motive power which stands for the *vis a tergo*, the vital energy, the life force of which we have spoken heretofore. It is thus seen that the genetic, energic conception of libido has taken the place of the descriptive definition of libido as given by Freud in his "Three Contributions to the Sexual Theory." Furthermore, Jung acknowledges that the earlier idea of the multiplicity of the sexual impulse must be discarded, that the earlier components represent nothing more than possibilities of activities, and that Freud erred in considering the sexual components practically as mental faculties. Jung has gone so far as to give what he considers to be the three phases of life from the standpoint of sexuality: (1) The first or presexual stage, occurring in the first years up to about three to five years of age, concerned almost exclusively with the functions of nutrition and growth; (2) the second or prepubertal stage, comprising the later years of childhood up to puberty, and (3) the third stage or the stage of maturity, which extends from puberty onward.

Freud's latent sexual period, which follows what Freud regards as the infantile sexual period, is for Jung the real beginning of sexuality and corresponds to what Jung is pleased to call the second or prepubertal stage of life, which is preceded by the presexual stage. Jung believes that the observations of Freud were faultless but that his conception was erroneous. We note, however, that the parent, or nuclear, or root complex (called the mother or Œdipus complex in the case of the son and the father or Electra complex in the case of the daughter) is for Jung the central point in the life of the individual. Although he differs from Freud by substituting his theory of regression (which to him is secondary phantastic dramatization) for Freud's theory of fixation and repression, nevertheless, we find that his standpoints are much the same as those of Freud with respect to the rôle of the parent complex. Jung believes that the incest complex is present in all of us, but that it is pathogenic or leads to trouble only when it becomes dynamic, with resulting conflict. "We do not ask any longer if the patient has a father- or a mother-complex, or unconscious incest phantasies which may worry him," says Jung. "To-day we know every one has such things. The belief that only neurotics had these complexes was an error." Furthermore, according to Jung, the incest complex exists even in persons who have never known their own mother or father, but were educated by step-parents, which, he says, is good proof that "the incest complex is much more a purely regressive production of phantasies than a reality."

At an earlier point Jung refers to this incest complex as a tendency which, in Freud's opinion, is a concrete wish, but which is unconscious due to repression by incest-barriers built up by experience and reality, comparable to the incest-taboo among primitive races. Jung's conception differs only in the substitution of his theory of regression with the reanimation and exaggerated activity of reminiscences of infancy and childhood, with the secondary phantastic dramatization. At one point, however, he does say: "Of course, for the child itself the mother has in this early stage no sexual significance of any importance. The term 'Œdipus complex' is in so far not really suitable." It is the protection and food afforded which is really responsible for the pleasure and delight which the child receives and he admits that the desire for food and protection (which means self-preservation) play a rôle. But Jung does not develop this idea, and his subsequent treatment of the terms "Œdipus complex" and "Electra complex" is in the usual Freudian (sexual) sense.

What is a Sexual Tendency, According to the Freudian School?—It may with justice be asked, what then is included within the conception of sexuality, or the sexual impulse, or instinct, when Freud or his followers speak of sexuality? How does Freud, or Jung, or any of the other members of the Freudian school define a sexual tendency?

Jung has defined a sexual tendency as "a standing still, a retardation in that process whereby the libido frees itself from the manifestations of the presexual stage." This definition can not be understood unless we use the term libido in Jung's sense and translate this definition in the light of what has gone before. Even then, however, this definition is for me quite vague and indefinite. It is plainly seen that there is now difference of opinion among the members of the Freudian school as to what should and what should not be included within the scope of the sexual impulse. There are contradictions to be found in reviewing the opinions of the various adherents of the fundamental Freudian theories. And in general it must be said that one hardly knows what a particular Freudian means when he refers to anything as having a sexual meaning.

Some of the meanings which sexual may have are the following: Normal mature heterosexual relationship, masturbation, incomplete coitus, interrupted coitus, ordinary sexual perversion, homosexuality, cravings of a sexual nature, pleasurable gratification or yearning for same, bodily heaving and surging, sense craving, longings and ambitions of whatever nature, the vital energy or vital impulse which is more or less synonymous with Jung's libido, Bergson's poussée vitale or élan vital, Schopenhauer's Wille zum Dassein or will to live, Nietzche's Wille zur Macht or will for power, and what we have been for some time calling the *vis a tergo*. There are other meanings which the sexual tendency may assume according to the writings of the Freudian school, but we have enumerated the most usual or most important ones in the review thus far given in this paper. He who runs may thus see that the sexual impulse or tendency has taken on, at the hands of Freud and his followers, a mystical, ambiguous, vague, indefinite, even metaphorical and metaphysical meaning. One may see, too, that at first a purely psychosexual conception was adopted. A gradual broadening out, necessitated by opposition and difficulties encountered, resulting in the assumption of a more racial and biological viewpoint, with certain definite drawbacks and distorted viewpoints.

General Criticisms of the Biological Conception Forced Upon the Freudian School.—But even the forced biological conception would not account for the energy in inorganic activities and for the organic activities which at present arise and at some time eons and eons of years ago most probably arose in the course of evolution from the inorganic. In inorganic processes reproduction is not the goal, and can be so made only if we assume that life activities, particularly as manifested in the higher forms of organic, especially animal life, are the natural and necessary and biological goal of inorganic activities. This assumption seems to me unwarranted, for a number of different reasons which I need not here enumerate, since I would be compelled to digress very widely from the subject under consideration. In a general way I may say that by holding to such an assumption and standpoint, we would be clinging tenaciously to an argument based upon facts which do not make the issue clearer and which compel the adoption of a onesided and not truly impartial and scientific outlook upon the various activities, in the inorganic and organic world, which surround us on every hand.

We must not forget to remind ourselves, in this connection, that all pleasurable feelings, surgings, etc., can by no manner of means be grouped as sexual from the individual (present life history) or the racial (truly biological—ontogenetic and phylogenetic, evolutionary) standpoint, unless we assume that all the manifestations of energy which come to the surface in our present or past lives are but the offshoots from that reservoir, or stream, or fountain, or what not of energy which has race-preservation or reproduction as its one and only ultimate goal, with sexuality, or the sexual impulse, or instinct, as the driving force which has fought its way up through evolution from the lowest to the present highest rung.

The genetic—evolutionary, ontogenetic and phylogenetic—psychobiological interpretation is the only broad and true rock upon which we can lay our groundwork and build a superstructure. And we name a thing not according to its end, but its beginning. This is the method we have pursued throughout science. For example, men belong to the animal kingdom and may appropriately be referred to as animals, but animals cannot and are not called men. Freud has, as mentioned above, permitted sexual to include all the stirrings of the infant and child before the development and activity of the normal, mature sexual impulse, on the ground that they were the proximate elements which became unified into the later mature instinct, and he has also forced within the confines of sexuality all the stirrings which beset man subsequent to the appearance of the sexual impulse in what he have come to look upon as the normal form or method of activity, on the ground that they are the offspring of this same sexual impulse. If we extend the individualistic and psychological standpoint, assumed by Freud, to a racial and broad, biological one, and view all activities in the same light, one can see that, if we once for all agree that race-preservation or reproduction is the one goal of all earthly activities and processes, of whatever nature, we have here presented to us a very nice and accommodating way of making the sexual impulse the goal as well as the origin of whatever is, was, or will be in the universe. But even here, although granting for the moment, for argument's sake, that this conception is sound and rational in every way, and is technically and theoretically unassailable, we shall find that for practical working purposes we would have to consider things in a different light, paying attention to the present life, purely psychological and individualistic meaning, in addition to the past life, biological and racial meaning. In other words, although admitting that from a racial, biological standpoint such and such a function or activity has such and such a meaning, yet we must understand that from the individualistic, psychological aspect it has such and such a significance. For example, although admitting, for the sake of argument, that all pleasurable feelings have biologically and racially a sexual significance, we can not go further and say that for this same reason all pleasurable feelings have the same psychological meaning to each separate individual and are sought for with this end, more or less consciously, in view. Thus even though all sexual feelings may be pleas-

urable (which they, in fact, are not), not all pleasurable feelings are sexual.

I shall not attempt at this point to circumvent the argument I have just given in support of the Freudian attitude, even biologically stated, but I must say that the primordially older tendency should be the landmark; and, in viewing things in our present or evolutionary life history, names assigned or significances attached to certain activities or processes should be given with this genetic conception in mind. In this connection it may be argued that race preservation or reproduction is but a means of self-preservation or self-expression, the former really being, essentially and fundamentally, but a means of self-preservation projected into the future. But, *per contra*, our opponents may return with the reply that self-preservation is but a means toward reproduction or race-conservation. Both sides would, in fact, be arguing in a circle. Both sides would be right. The real difference would be one of viewpoint, of interpretation. Once general agreement or mutual disagreement had been reached on this first point, subsequent agreement on all other questions could be arrived at. And yet it is this very issue which is at the basis of the whole problem, which has been buried in an avalanche of inconsequential details, of useless discussions, of misunderstandings, of evasions of the real issues and problems. Many have lost sight of the fact that quibbling and splitting of hairs where such quibbling and splitting of hairs are not called for and are as a matter of fact based on wrong premises or one-sided side-tracking, befog issues and delay approach to rational attitudes. Both of the primary or fundamental goals of self-preservation and race-preservation must receive due consideration; neither of them can be eliminated to favor, unnecessarily and unscientifically, the other.

As an illustration of the conclusions to which one may be led by partial viewpoints or dogmatic conceptions, we may mention that if the biological goal of all function is reproduction, and if all pleasure, bodily craving, etc., are but offshoots of the sexual impulse which supplies the motive power to reproduction, self-preservation—that is, the bodily demand or yearning for nutrition and growth, roughly called hunger—would be a portion of race-preservation, or reproduction; or, reducing it to terms of sexuality, of sex-gratification. Jung appreciates the incongruity of such a peculiar and artificial viewpoint of life and all that it stands for, and naturally finds that he must discard such a baseless and stunted scrutiny of all things from a sexual aspect, in a sexual setting, however far fetched the interpretation may be.

We do know that many functions of a nonsexual character (such as sympathy, love, maternality, art, music, mutual attraction and protection of offspring) are originally derived in a certain measure, in our present lives, from the instinct of propagation by the methods of sublimation or transference of energy from the sexual sphere to associated functions. This is true likewise in the history of the race—from the biological and evolutionary standpoint. But although these nonsexual characters may have arisen, in greater or lesser part, phylogenetically from sexuality, the energy being displaced or transferred from the instinct of propagation, nevertheless, from the standpoint of the psychology and the present life of the individual, they are not always sexual. Those tendencies or instincts are now existing in and for themselves, regardless of the phylogenetic origin. They were once upon a time but are not necessarily now, in greater or lesser degree, of sexual (or other primary) significance.

This idea of the sexual significance of love, sympathy, pleasure, and other nonsexual traits, may be compared to the James-Lange theory of the emotions. Both of these are true phylogenetically, considering their origin in the history of the race. But they no longer are absolute laws for the individual. For example, the energy expended in the care and protection of the young is to a great extent biologically and phylogenetically of sexual (race-preservative or reproductive) significance, but for the individual it cannot be said to be sexual. Nor can we say that it exists as such in the unconscious, if "unconscious" is to have a real meaning to us. Pregnancy is, for humans, a *sine qua non* for race preservation. It is a portion of the reproductive act. In this sense only has it a sexual meaning. Yet it cannot be said that for this reason pregnancy is a sexual act in the usual sense in which the word sexual is used (for the physical relation between the sexes, with the generative organs as the means of relationship).

Without attempting to combat the biologically sexual significance of love, sympathy, and other nonsexual traits, I would remind the reader that the self-preservation motive cannot be entirely ignored in favor of the reproduction or race conservation motive. See, for example, the late Christian Herter's "Biological Aspects of Human Problems" and Mercier's "Conduct and Its Disorders, Biologically Considered."

Freud includes all nonsexual functions or tendencies, however remotely allied to sexuality, as sexual, without endeavoring to prove them to be of a sexual nature. Thus all pleasurable feelings are classed as sexual, whether of a bodily or psychical nature, and all emotion and affection, intrafamilial or extrafamilial, is classified in the same way. It is true that Sanford Bell[14] has shown that all the emotions of normal love are very frequently experienced by boys and girls under the age of puberty. But, as Havelock Ellis[15] says, Bell's observations are confined to the psychic side of the children's lives, and consequently do not in any way indicate to what an extent such emotions occurring in childhood are specifically sexual in nature. In fact, we may agree with Ellis that specific physical manifestations in the generative sphere are comparatively uncommon in normal children. Furthermore, even though a very acute sensibility to the emotions of love may occur in childhood, still no consciousness of any specific localized sexual sensations can be proven to be present.

That many Freudians have forgotten the rôles which the play instinct or impulse and the desire for knowledge (curiosity) play in many of the acts of children should be apparent to all who have taken the trouble to learn their views. Many of the acts of children which may seem to the mature adult to be indicative of vicious sexual motives are frequently found, as a matter of fact, to have no sexual motive behind them at all. These activities depending upon the play impulse and the desire for knowledge may be entirely innocent and natural.

Let me hasten to add that the play impulse and the desire for knowledge or investigation cannot be explained biologically and phylogenetically as solely dependent upon the reproductive tendency. They can perhaps just as often be shown to have arisen from the self-conservative impulse. At any rate,

their origin is by no means simple, and several contributing factors can be shown to play a part in the ultimate genesis. Whatever their first beginnings, these activities are now frequently exercised in and for themselves, for one purpose or another.

Were it our object to follow up these remarks and to disprove the Freudian contention and demonstrate its false conception of life and of man in general, we could take up for separate consideration the various instincts, impulses, tendencies, or trends, physical, psychical, or psychophysical, conscious or unconscious, at every stage in evolution and development, in men and animals, and the various rungs in the organic world, and analyze these specific qualities with the ultimate object of arriving at the genesis and evolution. That this is not the place for such analyses seems to me self-evident.

It cannot be expected that each of the points in the conceptions of Freud and Jung, and their respective adherents, should receive extended discussion in this paper. Many of Freud's one-sided concepts are exploded even by Jung himself. In fact, the brief outline of the development and changing views of the Freudian school is alone sufficient to show the glaring misconceptions of the great majority of the members of the Freudian school.

It will, it seems to me, be quite sufficient for me to mention, in running fashion, wherein Freud and his followers have been in error in certain specific portions of their sexual theories.

Criticism of Freud's Conception of Infantile Sexuality.—Consider, in the first place, their concept of infantile sexuality, or sexuality in the infant and the child. None of the Freudians, except Jung, has mentioned anything other than sexuality in the life of the infant and child (and, as a matter of fact, in all of us). According to this idea, therefore, there is nothing but sexuality in infancy, childhood, and the subsequent periods of an individual's life. All activities and processes are but manifestations of this sexuality. But, although more as an argument to counteract criticism and to cloud the real issues, a biological standpoint has now and then been by pure compulsion seized upon for support, the sexuality really spoken of and harped upon and made the be-all and the end-all of existence for man at every stage of his development, is not biological sexuality, but the simon-pure, ordinary, hyperemotional, surging sexuality which is generally accorded by all scientific individuals to the term sexuality. Does not Jung[17] himself specifically state that for Freud the incest complex is a concrete sexual wish? True enough, the infant and child does not know what these feelings are, or does not regard them (if at such an age the individual can with clearness regard anything of real value in life) as sexual. They are, as the Freudians insist, but the adult (Freudian) view of things. But this adult (Freudian) view is the gross sexual, just as we all know it. It may expend its energy in the so-called erogenous zones, in polymorphous perverse sexual practises, in bisexual leanings, in incestuous cravings toward the various members of the family, but toward the parents in particular, in so-called Narcissism or self-love, or in one or another of many different ways. But it is the gross sexual meaning which is referred to in all of these manifestations, and as proof of this statement the reader is referred to the analyses of the cases as they are presented by the Freudian school. It is what we have been accustomed to look upon as the basest and most degrading sort of sexual gratification to which the foremost Freudians both here and abroad have reference. If any Freudian will dispute this claim I must refer him to a book which is supposed to give the gist of Freudism, namely, Hitschmann's "Freud's Theories of the Neuroses."[18] The writing on the wall allows of but one interpretation, and this is the interpretation which the Freudians carry out in their practical work. The resort to the claim that these wishes or desires or tendencies are unconscious, infantile, immature, and the like, does not interest me here. No matter where the wish or desire or tendency may be located, and no matter what its degree of intensity or development, it is the ordinary, usual, mature, gross form of sexuality of one kind or another which is meant by Freud.

What the Freudian school calls the erogenous zones are parts of the body where the infant practises autoerotism, analagous to masturbation, with the object of obtaining a certain measure of pleasure of a sexual nature. The error of Freud patent in this connection may be explained as follows: Zones which may later on in life be used for sexual purposes, in addition to their ordinary and original functions (and, it must be interjected, that there is no portion of the surface of the body which may not thus be employed), have had sexual gratification and sexual activity assigned to them as the primary, original, and natural function. And for this reason they have been called erogenous, when they should really have been referred to as possibly erogenous at some time in the future, if we wished to mention, for some particular reason, such as, for instance, to explain the sexual aberrations, the sexual use to which this or that part of the body could be put. Of course the accompanying affect or feeling, not always of a sexual nature, although frequently so, has, by analogy with the sexual impulse, been made use of to support the sexual significance of acts of the most innocent nature and most necessary for the self-preservation of the race or the individual.

The most reckless and flagrant misconstruction of the child's activities has led to that most necessary and vital function as the sucking of the breast by the new-born babe to obtain the milk wherewith to live being very critically and microscopically viewed from the sexual aspect, with the neglect of all other meanings to the pleasure or emotion accompanying this act. This was the rock upon which was built the theory whereby all rhythmical activities, usually accompanied by a certain degree of pleasure and satisfaction, were also set in a sexual setting and with a sexual halo. Nay, more, sexuality was the real explanation for their *raison d'être*. This generalization, which had its first beginnings in the conception of erogeneous zones, has, to be sure, such a wide applicability that one is forced to the conclusion, if one carries this theory out to its most far-reaching significance, that all human activity and energy, hence all vital, which means the universal, energy is of a sexual nature. And if this idea cannot be supported by a psychological, individualistic conception, one must, as the Freudians found themselves compelled to do, assume, for protection's sake, a biological argument, although still adhering to the first concept in the practical application of their theories. Is it not plain that the erogenous zones of Freud are not at all erogenous zones, but merely parts of the body which may or can be used for sexual purposes at some future date in the course of the individual's life?

Since the erogenous zones are the basis for Freud's belief in the polymorphous perverse sexual predisposition or tendency of the infant, we may at once clear the boards of this conception, since the premises are groundless and false. Instead of insisting upon the polymorphous perverse sexual predisposition or tendency of the infant and child, and hence of the adult, one is more correct in speaking of the polymorphous perverse sexual possibility of man, whether infant, child, or adult. To this no one who gives this matter sufficient consideration would object. But it is a far cry from a possibility, which varies in degree in all individuals, and is dependent upon the instinctive make-up, the training and the life experiences, to a definite and undeniable predisposition or tendency. And in this theory, also, Freud has supported his argument by drawing an analogy between the actions of the infant and child and certain actions which the adult or more mature individual, with the sexual impulse more or less fully developed, may resort to as partial expressions or substitute expressions for or preliminary efforts at sexual gratification of the ordinary physical sort. Here, then, argument by analogy and the enveloping of infantile activities with future possibilities of a transient or temporary nature under special circumstance has led to a far-reaching and seriously distorted misstatement or misinterpretation.

No less significant is this indictment when we come to estimate the Freudian dictum of the bisexual and incestuous tendency of man as represented in the infant and the child. In the first place bisexual should be replaced by the term ambisexual. And tendency or predisposition should be replaced by the word possibility. Furthermore, in the erection of the theory of bisexuality and incestuousness the psychic manifestations of emotions of affection and of attraction and repulsion between the infant or child and those with whom he comes in contact have been classified as sexual. This classification is based on the analogy between all affectivity or feeling and the sexual feeling in particular, and on certain possible sexual relationships which are present to the mature, sexually developed adult.

At this point it may be worth while mentioning that in the concept of the incest or parent complex, called the Œdipus and Electra complex, as previously explained, we have definite proof that it is the usual gross, physical meaning of sexual which is understood by Freud and his followers when they use the term sexual. Of course one could offer pages of evidence from the writings of Freudians to prove this. But here we have definite, incontrovertible evidence. Œdipus, owing to certain peculiar circumstances explained in the footnote,* unknown to himself committed incest by marrying his mother. Electra,† in revenge for the murder of her father by her mother, assisted her brother in slaying their mother. In the case of Œdipus there were definite sexual relationships. In the case of Electra the Freudians insist that it was because of the desire for sexual relationship with her father that Electra was prompted to urge her brother to commit the murder in which she assisted him. Other motives are disregarded. The attending circumstance in each case are relegated to the limbo of the non-essential and the insignificant. And upon this as a foundation Freud and his school have built up their theory of incest complex, which is nothing more nor less than a concrete sexual wish. And it is in this way that so much of the conduct and tendencies of the growing child are explained. Other meanings, other interpretations, other origins are calmly but positively ignored. And, let me hasten to mention, with this beginning it is no wonder that all human relationships, intrafamilial or extrafamilial, intimate or remote, all reactions and attitudes, all attraction and repulsion, are viewed in the same light and given the same sexual significance. That such a theory would lead one to an inevitable *reductio ad absurdum* goes without saying.

The theory of Narcissism‡ or self-love next pre-

*William Smith's "A Smaller Classical Dictionary," pp. 364-365, Everyman's Library, gives the following account of Œdipus: Œdipus, son of Laius, king of Thebes, and of Jocasta, sister of Creon. His father having learnt from an oracle that he was doomed to perish by the hands of his own son, exposed Œdipus on Mt. Cithæron, immediately after his birth, with his feet pierced and tied together. The child was found by a shepherd of King Polybus of Corinth, and was called from his swollen feet Œdipus. Having been carried to the palace, the king reared him as his own child; but when Oedipus had grown up, he was told by the oracle at Delphi, which he had gone to consult, that he was destined to slay his father, and commit incest with his mother. Thinking that Polybus was his father, he resolved not to return to Corinth; but on the road between Delphi and Daulis he met Laius, whom he slew in a scuffle without knowing that he was his father. In the meantime the celebrated Sphinx had appeared in the neighborhood of Thebes. Seated on a rock, she put a riddle to every Theban that passed by, and whoever was unable to solve it was killed by the monster. This calamity induced the Thebans to proclaim that whoever should deliver the country of the Sphinx, should obtain the kingdom and Jocasta as his wife. The riddle ran as follows: "A being with four feet has two feet and three feet, and only one voice; but its feet vary, and when it has most it is weakest." Œdipus solved the riddle by saying that it was man, who in infancy crawls upon all fours, in manhood stands erect upon two feet, and in old age supports his tottering legs with a staff. The Sphinx thereupon threw herself down from the rock. Œdipus now obtained the kingdom of Thebes, and married his mother, by whom he became the father of Eteocles, Polynices, Antigone, and Ismene. In consequence of this incestuous alliance, the country of Thebes was visited by a plague. The oracle, on being consulted, ordered that the murderer of Laius should be expelled; and the sere Tiresias told Œdipus that he was the guilty man. Thereupon Jocasta hung herself, and Œdipus put out his own eyes, and wandered from Thebes, accompanied by his daughter, Antigone. In Attica he at length found a place of refuge; and at Colonus, near Athens, the Eumendes removed him from the earth. The tragic fate of Œdipus and of his children formed the subject of many of the noblest of the Greek tragedies. Among these the first place must be assigned to the splendid trilogy of Sophocles, Œdipus the King, Œdipus at Colonus, and the Antigone.

†William Smith's "A Smaller Classical Dictionary," pp. 204-205, Everyman's Library, gives the following account of Electra: Daughter of Agamemnon and Clytaemnestra, also called Luodice, sister of Iphigenia and Orestes. After the murder of her father by her mother, she saved the life of her young brother Orestes by sending him to King Strophius until he had grown up to manhood. Electra then excited him to avenge the death of Agamemnon, and assisted him in slaying their mother, Clytaemnestra. After the death of the latter, Orestes gave her in marriage to his friend Pylades. Sophocles's "Electra" is based on this story.

‡William Smith's "A Smaller Classical Dictionary," pp. 351-352, Everyman's Library, gives the following version of the story centered about Narcissus: Narcissus, a beautiful youth, son of Cephissus and Liriope, was inaccessible to the feeling of love; and the nymph Echo, who was enamored of him, died of grief. But Nemesis, to punish him, caused him to see his own image reflected in a fountain, whereupon he became so enamored of it that he gradually pined away, until he was metamorphosed into the flower which bears his name.

sents itself. All evidences of love of self, of exaggerated ego, of self-esteem, of self-satisfaction and the like, are believed by Freud to be sexual in meaning. As outlined previously, when we considered Freud's theory of sexual (which to him seems to mean human) development, the road to homosexuality and thence to heterosexuality lies through or is by way of Narcissism, which is the step that succeeds autoerotism. This Narcissism is definitely sexual. And, by virtue of an ingenious theory of reflected self-love, there are a host of tendencies which are said to be derived from the Narcissistic tendency, which, as stated, is sexual. There is so little proof for such an ill-founded assumption and dogmatic conclusion that it almost seems to me that it does not really warrant serious consideration. The amount of evidence in controversion of this idea is voluminous. I need call attention to but one complication to which one would be led if he believed in this theory, and if he would be thorough and carry it out to its final conclusion. All efforts for self-expression and self-preservation may be said to be, in a biological sense, evidences of self-love. In this way self-preservation is but a portion of self-love. If we substitute for this biological and evolutionary viewpoint, the psychological and individualistic one, which is that employed by the Freudian school in all their practical work, then all effort of the individual is but an indication of self-love. And since the latter is of sexual significance, so is the former. And this latter sexual significance is but an evidence of sexuality, as this term is ordinarily employed. The fallacy of this is, I surmise, self-evident.

Jung's efforts to extricate himself from the network which in the course of time has entangled the Freudian school and buried it beneath the superstructure which was built up and which now hangs most heavily upon its tottering and top-heavy foundations, do not, in my opinion, clear the atmosphere or brush away the cobwebs. He discusses certain technical points which still leave the main issues untouched. The vital energy, he is willing to agree, is not sexual. The pleasure accompanying the act of sucking necessary for nutrition in the infant, and hence all pleasure, is not sexual. But practically all subsequent rhythmical activities accompanied by pleasure and satisfaction may be compared to masturbation, and in his presexual stage (see above, under Jung's modification of Freud's views, for his three phases of life, from the sexual standpoint) there is a gradual transition from their nutritional (that is, self-preservation) connotation to their sexual meaning. In fact, they are the means toward definite sexual expressions, and hence had best be called presexual instead of sexual. Furthermore, since this is the normal process with all individuals, these early expressions or precursors of sexuality should not be called perverse, since, in the strict sense, a sexual perversion is a disorder of fully developed, mature sexuality, and, to speak more correctly, the infantile and early childhood activities of which we are now speaking are really only possible perversions. In other words, it would seem, from what I understand, that if, as I have suggested previously in this paper, the word possibility were substituted for predisposition or tendency, the phrase polymorphous perverse sexuality would not be objected to by Jung. Or we were to substitute the phrase infantile polymorphous sexuality or presexuality, thus making no mention of perversity, there would apparently be no objection on the part of Jung. That he still maintains the sexual viewpoint of life's (including the infant's) activities may be seen from the fact that he divides human life into three (sexual) periods, named, as heretofore given, the presexual, prepubertal and mature stages.

Fundamentally, therefore, the life history of the individual is practically entirely sexual for Jung. He is no more justified in classifying the sucking of the mother's breast by the infant in the process of nutrition as non-sexual than he is justified in grouping later, similar activities as presexual or sexual. Reasoning and proof by analogy seem to have and hold their place in Jung's scheme of the child's functioning, so far as I understand him.

Likewise, his substitution of his theory of regression with the reanimation and phantastic and secondary elaboration or dramatization for Freud's theory of fixation and repression in the matter of the incest complex is not *à propos* the vital issues thus far delineated.

Although discussing at some length the biological aspect of the sexual instinct, he practically gives this up in his discussion of infantile sexuality, in its psychological and individualistic bearings.

Neglect of the Evolutionary Standpoint.—Now, there is no more serious defect in Freud's theories than his neglect of the phylogenetic and evolutionary outlook upon life and man. This, in truth, has been the hidden rock upon which Freudism has foundered. So important is this deficiency in Freudism and so much is it responsible for the errors and difficulties of the Freudians, that it will not be out of place to mention a few particular instances of what I mean.

In his discussion of sadism and masochism, Freud says: "The roots of active algolagnia, sadism, can be readily demonstrable in the normal. The sexuality of most men shows a taint of aggression. It is a propensity to subdue, the biological significance of which lies in the necessity of overcoming the resistance of the sexual object by actions other than mere courting. Sadism would then correspond to an aggressive component of the sexual impulse which has become independent and exaggerated and has been brought to the foreground by displacement."[1]

The fact that sadism may have originally arisen in connection with self-preservation, and may later be linked with the sexual impulse, so that this aggressive tendency present in sexuality may be but a special application of the tendency for self-preservation by any means, no matter how primitive, brutal, barbaric or primordial, receives no mention in Freudian literature (so far as I am aware) except by Freud himself, who, although he seems to have for a moment grasped the phylogenetic concept, never mentioned it again, so far as the writer knows. This single reference that I find is as follows: "The aggression which is mixed with the sexual impulse is, according to some authors, a remnant of cannibalistic lust, a participation on the part of the acquisition apparatus (Bemächtigungsapparatus) which serves also for the gratification of the great wants of the other, ontogenetically the older impulse."[2] But even here the Freudians may now argue (and this in spite of the theory that ontogeny recapitulates phylogeny) that even though this may be true ontogenetically, it is not true phylogenetically, since, basically, sexuality is "the string that runs through the pearl of all virtues." Freud's explanation of passive algolagnia or masochism could also be cited here. And in further proof, Freud's explanation for infantile and childhood fear is most

illuminating on this very point: "The fear of children is originally nothing but an expression for the fact that they miss the beloved person. They therefore meet every stranger with fear; they are afraid of the dark because they cannot see the beloved person, and are calmed if they can grasp that person's hand."[2] The disregard of or indifference toward the nature and origin and existence of instincts in the life of the race is noteworthy.

It is not out of place to direct the reader's attention to the truism that what is basically true in the life of the race is likewise fundamentally true in the life of the individual. The main, basic trends are transmitted in some measure. And, vice versa, what is universally and without exception true for all mankind, at every stage of development, is also true, in some measure, for the race, and finds its *raison d'être* in instinctive, inherent, germinal tendencies. I mention this because the Freudian school has found certain principles or tendencies of universal and fundamental significance, and at the root of all activities of man, whether infant or adult, normal or abnormal. These basic truths must be founded upon germinal, instinctive tendencies. Consequently the polymorphous perverse sexual, bisexual, incestuous and Narcissistic predispositions or tendencies of the Freudians must be of a germinal, instinctive derivation. If the Freudians are not in error, these tendencies or possibilities are nothing more nor less than instincts. This is the conclusion to which, I believe, one is led by adopting the Freudian ideas. To discuss this question is not in order at this time.

Although there is much scientific proof for the contention that not only is sex-gratification but a portion and means of self-expression or self-preservation or the gratification of the personal tastes and feelings in the life of the individual, but also that race-preservation or reproduction is but a means of self-preservation in the life of the race, I shall present no further proof for this conception than the two references in the attached footnote.* There are, in addition, many weighty arguments which could be offered to bolster up this assumption. As has been asserted previously, however, there is no need to split hairs in a narrow-minded fashion when in search of truth. It is absolutely immaterial to me what instinct or motive is given the most credit so long as, in each individual case under consideration, an impartial, truly scientific weighing of the facts is pursued and credit given where it is due, regardless of any special theories or dogmata which one or another set of thinkers may have put forth.

Without minimizing the value and full import of the movement set on foot by Freud, Jung, and others, with due appreciation of the analytic, dynamic, energic conception (which surely was nothing new or original with Freud or Jung), with full recognition of their efforts in dissection of the sexual life and the sexual impulse and of their efforts to determine the rôle, the genesis, the evolution and the goal of the sexual instinct, and with approval of the genetic standpoint in psychiatry and physchopathology (which tendency, also, was not unheard of before, as witness the genetic psychologists, and others), we must, nevertheless, without prejudice or animosity, take note of the defects in the Freudian conception of the sexual instinct.

Most to be criticised is the exclusively individualistic and narrow psychological standpoint—the psychosexual viewpoint—of life and all its manifestation, including man, and, in particular, the infant and child. It is this which led to the use of the term "predisposition" and "tendency" instead of "possibility," of erogenous zones, of the bisexuality and incestuousness and polymorphous perverse sexuality and Narcissism of the infant and the child, to the use of the term sexual to include all pleasurable activities, all feelings, tendencies, and instincts, so that, in the end, it was synonymous with the vital energy of the universe, necessitating the efforts at defense and the adoption of such terms as libido, presexual, and the like, which merely complicate the situation without clearing up the basic errors.

The sexogenetic or psychosexogenetic view must be replaced by a broad psychogenetic or psychobiogenetic one, which will include within its scope not only the present life of the individual, but the past life, the world history of man and of life, with the racial (ontogenetic and phylogenetic), biological and evolutionary approach to the problem of energic manifestations.

Self-preservation, ontogenetically, at least, the older impulse, should be given that degree of consideration which it most surely deserves.

In brief, the Freudian school must get away from their conception of pansexuality, which has been carried out so persistently that to the writer it seems that when a Freudian uses such terms as wish, instinct, tendency, trend, meaning, motive, desire, longing, yearning, psychic, unconscious, repression, fixation, regression, sublimation, transference, conversion, substitution, affect, libido, symbolism, content, and the rest, the sexual implication is practically always silently understood or indirectly hinted at—if not openly, then by innuendo or by what has gone before in the same article or in previous articles.

*In his Lowell lectures on "The Ascent of Man," p. 225, published in 1894, Henry Drummond presents the following splendid description, which could be employed to support the thesis that reproduction is a portion of self-preservation: "Watch one of the humblest unicellular organisms at the time of reproduction. The cell, when it grows to be a certain size, divides itself into two, and each part sets up an independent life. The protoplasm inside the cell—the body as it were—needs continually to draw in fresh food. This is secured by a process of imbibition or osmosis through the surrounding wall. But as the cell grows larger, there is not wall enough to pass in all the food the far interior needs, for while the bulk increases as the cube of the diameter, the surface increases only as the square. The bulk of the cell, in short, has outrun the absorbing surface; its hunger has outgrown its satisfaction; and unless the cell can devise some way of gaining more surface it must starve. Hence the splitting into two smaller cells. There is now more absorbing surface than the two had when combined. When the two smaller cells have grown as large as the original parent, income and expenditure will once more balance. As growth continues, the waste begins to exceed the power of repair and the life of the cell is again threatened."

Hence, as Geddes and Thompson, in the "Evolution of Sex," p. 232, say: "Reproduction begins as a rupture. Large cells beginning to die save their lives by sacrifice. Reproduction is literally a life-saving against the approach of death. Whether it be the almost random rupture of one of the more primitive forms such as Schizogenes, or the overflow and separation of multiple buds in Arcella, or the dissolution of a few of the Infusorians, an organism, which is becoming exhausted, saves itself and multiplies in reproducing."

Here, surely, is a splendid argument to show that reproduction is dependent upon and is a part of the process of nutrition and self-preservation, and that the self-sacrifice involved in reproduction is originated from self-preservation. In this way one could build up a beautiful theory by which all self-sacrifice and altruism, all feelings and tendencies derive their ultimate motive powers or springs of energy from the self-preservation or nutritional instinct.

The first step in this direction consists of a proper understanding of man's place in nature and of the instinctive make-up of human beings. Whether or not we agree with William McDougall's classification and explanations, his "An Introduction to Social Psychology" is a good working basis upon which to build. The genetic psychologists are opening up the way to greater fields and pastures new. It gives me great pleasure to mention, in this connection, G. Stanley Hall's illuminating and stimulating series of papers in the *American Journal of Psychology* (beginning April, 1914), entitled "A Synthetic Genetic Study of Fear."

In conclusion the writer wishes to assure the reader that the above fragmentary and brief remarks of a superficial and critical nature are offered not with the object of narrow-minded, bigoted criticism, or of depreciation of the actual benefits to psychoanalysis, psychology, psychopathology and psychiatry derived from the Freudian movement, directly or indirectly.[37]

The writer will be pardoned for not giving personal opinions or for not attempting to give his or others' theories concerning such important problems as the origin and nature of instincts, feelings and the general tendencies of mankind, concerning the origin and development of the family and of the other qualities and relationships mentioned here and there in this paper. Such a discussion would be too far-reaching for appearance in a medical journal, and would be too much to ask in a paper of the kind I had in mind when I decided upon the one here offered.

Obviously, since the sexual theories of Freud are so intimately bound up with all the other theories enunciated by Freud, and, in reality, are the stuff whereof the Freudian psychology and the Freudian method of and standpoint in psychoanalysis are made, we are, in this discussion, striking at the very roots of the tree which sends its branches (the other theories) upward in all directions.

The term "psychoanalysis" is used by the writer in the broad, unrestricted sense of the word—as being synonymous with mental analysis, by any method or from any standpoint. No indictment can be made against psychoanalysis in general because the Freudian method and standpoint in psychoanalysis, being based upon the theory of pansexuality, has been sidetracked into sexoanalysis and sexopsychology.

A NEW OPERATION FOR FISTULA IN ANO.

BY S. J. BLUMENTHAL, M.D.,

BROOKLYN, NEW YORK.

ATTENDING PHYSICIAN TO THE EASTERN DISTRICT DISPENSARY AND HOSPITAL MEDICAL CLINIC.

IN advancing a new operation for the complete and blind external varieties of fistula in ano I do not propose to do away with the old operation. Each shall have its own particular field of usefulness as will readily be gleaned by a perusal of the procedure.

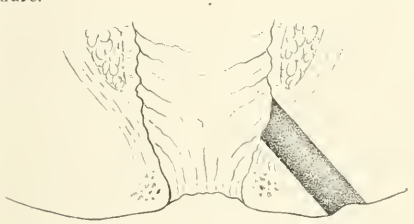

FIG. 1.—Sphincter of rectum dilated, fistula curetted.

The advantages claimed over the old operation are: (1) The sphincter ani is not cut. (2) No large raw surfaces to heal. (3) Healing under clean conditions. (4) Action of sphincter never impaired. (5) Fistula practically sterile before collapse. (6) No scar on surface afterward. (7) Knife not used at all. (8) Bloodless operation. (9) Operation of choice in young fistulæ. In order to obtain good results with my technique special instruments will be required and the technique closely scrutinized. The advantages to be gained warrant the special instruments.

Instruments.—(1) Probe. (2) Thin, straight sound. (3) Sharp curettes. (4) Twenty-day chromic suture, heavy. (5) Rectangular hard-rubber plate to conform in shape with the nates overlying the course of the fistula. Width of fistula plate will vary with the distance the fistula is removed from the surface of the skin. The deeper the fistula the wider the plate, on account of the large sweep of the needle. Plate about one-fourth inch thick and double convex. (6) Large aneurysm needle with handle. (7) Small aluminum tube to fit over the Paquelin cautery so as to allow only about one-half inch of the bar to protrude (Fig. 4). (8) Paquelin or electric cautery. (9) Tincture of iodine. (10) Glass syringe, 10 c.c., for the iodine.

(11) A hard-rubber tube about 3 inches in height. The top, the size of a man's thumb; the base abruptly sloping in width. Two perforations at the base of the tube for a T-bandage. (12) Small calibered, silver tube, one-sixteenth inch wide, about

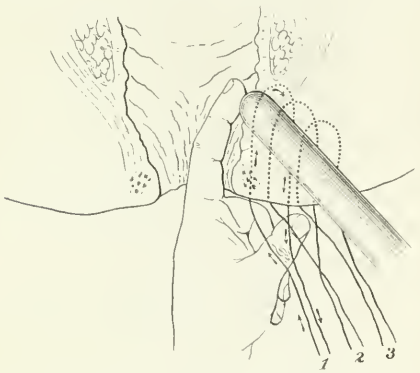

Fig. 2.—Sound acting as a guide for the sutures which surround it. The needle is entered about a half inch from the sound.

three inches long, with many perforations in its wall. One end tapers to a blunt point, while the other is wide enough to fit a suction pump. The tube is used for drainage, for irrigation, and for the production of artificial hyperemia by means of suction pump.

Preparation.—Prior to operation the patient's health should be improved as much as is possible. Suitable tonics given over a course of two or three weeks when feasible, better the outlook for a more speedy recovery. A certain amount of rest should be enjoined upon the patient.

Technique.—The whole of the following procedure can be done in a very short time. The patient receives an enema before being brought to the operating table. The anesthetic should be general. If tuberculosis of the lungs is present

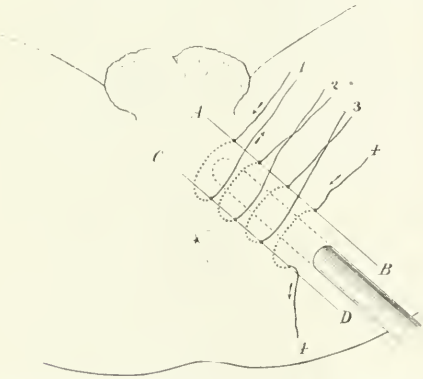

Fig. 3.—The iodine lines AB and CD are guide lines for the entrance and exit of the needle. These lines are drawn after suture No. 1 is put in, and run parallel to the sound, the distance between them being in accordance with the width of the plate selected.

chloroform or local anesthesia should be employed in preference to ether. The patient is placed in the lithotomy position. The fistula is on the left side for the sake of description. The anal orifice is thoroughly dilated manually. A probe is inserted to get the direction of the fistula. Then with a small but sharp curette remove the granulations from the wall of the canal and irrigate with saline solution. (Fig. 1.) Insert the straight sound. If the canal is curved, the sound straightens it out for

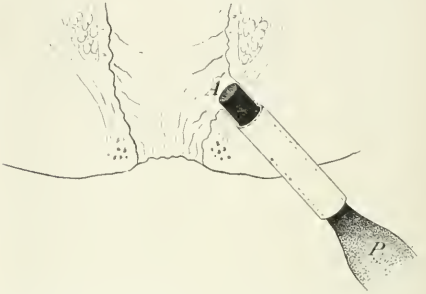

Fig. 4.—Shows the tube in place with cautery bar protruding; by rotating the handle P, the whole wall of the fistula is reached.

suturing. The sound acts as a guide for the course of the needle. If the rectal opening is not far removed the sound may be brought out from the rectal end. Suture No. 1 starts at a point a little higher than the sound. (Fig. 3.) Keep the needle always concentric with the sound and about one-half inch away from same. The point of the needle is brought out at a distance from the entrance to correspond to distance on the plate (Figs. 3 and 5). The eye is threaded with chromic catgut when it appears and is again withdrawn. In placing the first suture, when the sound is not brought out of the rectum, put the left index finger in the rectum and feel the tip of the sound. This maneuver helps to bring the suture as near the rectal membrane as possible, but not through it. Suture No. 1 is the most important suture because it must close off the fistula from the rectum. After the first suture is put in draw two parallel lines, A, B, and C, D, parallel to the sound in the fistula. These

Fig. 5.—Suture tied and cut; the arrows point to the collapsed fistula. The plate acts as a splint, compresses the entire fistulous tract, and prevents the sutures from cutting the skin.

lines are drawn with tincture of iodine. The intervals for sutures are also marked off according to the plate. With a little practice the surgeon can order a plate for each operation and avoid buying too many of them.

Line A, B designates the entrance of needle and line C, D the exit. The needle must never touch the sound in its excursion about it. Figure 3 shows the fistula surrounded by sutures—ends not tied.

Before cauterizing swab the tract with a 20 per

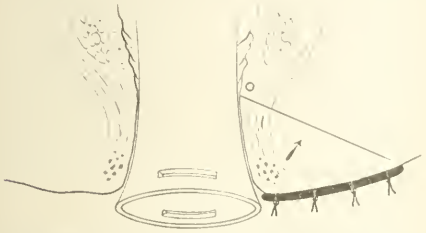

Fig. 6. Shows the plate pressing upon the fistula; the arrow points in the direction of pressure from the tube. The internal opening of the fistula, O, is kept by the tube from being soiled.

cent. solution of cocaine or novocaine in order to lessen the shock incident to cauterization of a large number of nerve endings. Whether we use electric or Paquelin cautery the walls of the fistula should not be left charred. Oozing is highly desirable, as it shows that the vessels of nutrition are not occluded. If this condition exists the curette will easily bring oozing. A piece of metal in the rectum opposite the fistula prevents burning of unnecessary tissues. By employing the tube over the cautery bar a small portion of the fistula is cauterized at a time, and it also permits the cauterizing agent to be very hot until the rectal end of the fistula is reached. This would be impossible without the tube. The tube is held *in situ* during cauterization by means of a convenient clamp. With a circular movement of the handle P about A (Fig. 4) the whole circumference of the fistula is reached. The tube is pulled out by degrees as the cauterization progresses. While the tube is being pulled into place the cautery is removed and again heated before using.

The plate is now threaded onto the ends of the sutures. It is obvious that when the sutures are tied the plate acts as a splint to the whole tract, thereby increasing its chances for primary union. It also prevents the stitches from cutting and giving stitch abscesses. The sutures are not tied until the next step is completed.

The operator closes the orifice of the fistula in the rectum (orifice found with the probe). While the operator holds his left index in this position the assistant forces tincture of iodine into the canal under pressure. The iodine reaches all trabeculæ and the tract is pretty well cleaned up. The iodine remains in for a minute or two, when it is washed out with saline solution. The iodine starts an adhesive inflammation.

Now the operator with his left index still unmoved inserts a probe to meet the finger, and tells his assistant to tie suture No. 1. When the surgeon feels the suture grasping the probe the knot is tied securely. After the knot is tied the probe cannot meet the rectal finger any longer. The rectal finger is now removed and the other sutures are tied in like manner. When the stitch starts cutting from the inside it mechanically stops as the suture is loosened just enough to prevent cutting further.

Due to the pressure of the plate (Fig. 6) the rectal mucous membrane is bulged inward. By using the tube this bulging is exerted up against the fistula. This tube also helps to keep the entrance to the fistula (O, Fig. 6) clear of fecal irritation. This tube is removed in three or four days, when healing commences. The tube should be held *in situ* by a T-bandage. In blind external fistulæ this tube is not required.

When the sutures are tied, insert the narrow drainage tube up to the second suture. Now this tube acts as a drain and permits the fistula to heal from within outward. The blood supply to the tract is poor. To get more blood to it suction a few times a day, commencing after a lapse of a few days, may be employed, thus producing an artificial hyperemia. This suction also cleans up the detritus. Irrigations with warm saline are in order every morning. The tube is daily pulled out a little more and tincture of iodine and water, equal parts, allowed to flow in to stimulate healing. No force should be employed in the injection, as the bridge of new tissue would be broken down.

The technique employed will of course vary with every case. In the blind external variety curetage, tincture of iodine, and plate with sutures may be all that will be required.

The principle of the operation is to remove the granulation tissue and to get primary union by collapsing the fistula at rest without mutilating the skin or sphincter in comparatively young fistulæ.

Patients will submit to early operations when we can assure them that no knife will be used nor a cut in the skin made. Thus early operation will stay the progress.

If the case is an old one, with its concomitant sinuses and thick resistant walls, the old operation had better be done, as my procedure would not open up the large sinuses.

The new ideas involved in this operation are the plate, peculiar method of applying the cautery, use of a sound for guiding the sutures in a fistula operation, doing away with the cutting of the sphincter in cases operable by this routine, producing hyperemia in a fistulous tract in order to get more nutrition to the part, and doing away with the knife in a major operation.

ANOSOGNOSIA AND ANOSODIAPHORIA.*

By E. Murray Auer, M.D.,

Philadelphia.

From the Department of Neuropathology, University of Pennsylvania.

The observance of a non-existing factor, like the non-observance of an existing factor, may be due to either an organic or functional nervous or mental disorder. It has long been known that irritative lesions of different parts of the nervous mechanism of the special senses occasion the production of pathological functional phenomena, just as a destructive lesion may cause a loss of the normal function of the sense affected. However in such an involvement the individual is invariably aware of either a hyper- or hypoactivity.

Recently Babinski[1] observed in two cases of organic cerebral hemiplegia that the patients ignored or appeared to ignore the existence of the paralysis with which they were affected. To this condition he gave the name anosognosia. In both of his patients the paralysis was of right sided origin, the

*Read before the Philadelphia Neurological Society December 18, 1914.

intelligence was unaffected, there was no notable uneasiness, no mental confusion or hallucinations.

In his first case, that of a woman with an almost complete hemiplegia of several years duration, the patient ignored entirely any request to move the paralyzed side and never spoke of her affection as such. In the paralyzed side tactile and pain sense were affected. Later grave mental disorders appeared and the patient died after being in a demented state for some time.

In his second case, also that of a woman, he described the patient as being continually a little excited and at that time holding conversations which seemed strange. When asked to move the paralyzed side she either ignored the question or replied, "There, it is done," without making any attempt to move it.

Souques in his discussion mentioned the case of a physician with a left hemiplegia and hemianesthesia who ignored entirely his paralysis.

Miege stated that while one frequently sees asphasic patients who lament bitterly their speech defect, one rarely finds a hemiplegic who complains of the loss of use of the affected members. He asks, "Is this resignation, desire to conceal from themselves or others an inferiority with which they are affected? It may be in certain cases, but in others one is dealing with a true psychopathic disturbance." His observations have lead him to admit the existence of a functional motor amnesia in hemiplegics.

Babinski further observed that some hemiplegics, without ignoring the existence of their paralysis, seemed not to attach any importance to it, as though affected with an insignificant disease. This he terms anosodiaphoria.

In an examination of seventy-six cases of hemiplegia by myself, there were several, more especially among the male patients, who, without attaching any great importance to their condition, conducted themselves in a fairly normal and contented manner in so far as their physical disability would permit. I found none who absolutely ignored or denied their conditon. Of the cases examined there were seven right hemiplegic with asphasia. None of these evinced an ignorance of either of their afflictions. There were five left hemiplegics that showed marked memory defects; but none had forgotten their paralysis. There was one right hemiplegic with no asphasia who showed mental deterioration but was aware of the paralysis.

Case I. H. W. Right hemiplegia. Patient states that when he is lying down he does not think his paralyzed side affected.

Case II. P. McK. Left hemiplegia. Patient states that his side never troubles him and that most of the time he wouldn't know it was there.

Case III. F. M. Right hemiplegia. Patient is only partially oriented and shows a memory disturbance. On questioning he states he is feeling fine and has nothing to complain of. Move your right arm. "I can't." "What is the trouble with it?" "Scraped it with an oil can." Further questioning does not bring out that he was paralyzed until asked point blank if he were not paralyzed, he replies "Oh yes, three years ago."

Case IV. E. S. Female with a left hemiplegia. Has complete loss of sensation of touch, motion, and position and stereognosis, but does not ignore or deny her paralysis.

Case V. M. H. Female with a left hemiplegia. Patient has lost sensation of touch, motion, and position. She freely converses of her diseased side.

Case VI. E. H. Female with left hemiplegia. When spoken to tells of attacks of vertigo and various ailments but makes no mention of her paralysis until asked to move the paralyzed arm whereupon she states, "It is paralyzed."

Barat[2] reported the case of a bedridden woman aged seventy-two with a left hemiplegia and totally blind. She believed she had nothing to complain of in regard to her vision or to the use of her limbs. She exhibited a mental defect and a tendency to substitute images of sensation and memory.

Noteworthy in my own examination is the observation that two left hemiplegics with pronounced sensory disturbances in the affected side evinced neither anosognosia or anosodiophoria; further, that those ignoring or denying their affliction showed mental deterioration and that those attaching little importance to their diseased side suffered little subjective sensory disturbance and had accustomed themselves to the loss of function of the affected parts, as is frequently observed in many individuals with chronic disease.

If the condition anosognosia were to be explained as a sensory disturbance why was it not present with complete loss of sensation? The fact that in right-handed individuals the left cerebral lobe is more highly specialized than the right would lead us to assume that if we were dealing here with a disturbance of association we would be more apt to find the condition in lesions of the left lobe.

In "vision nulle" we have a visual disturbance of which the patent is as manifestly ignorant as were these patients of their paralysis, and stress has been laid upon this as a symptomatic differentiation between a cortical and a subcortical lesion, as also have the hallucinatory disturbances occurring in lateral homonymous hemianopsia.

Claude and Rose[3] reported two cases of tumor of the occipital lobe in which there were no visual hallucinations. They assumed that visual hallucinations are due to irritation of the calcarine cortex and were absent in those cases because the tumors were in the white matter of the occipital lobe. Dr. W. G. Spiller[4] has reported a case of well pronounced visual hallucinatory disturbance in which autopsy examination showed a tumor in the lower part of the right occipital lobe.

According to Swanzy the chief diagnostic symptom of a cortical lesion is "vision nulle"; the patient, though he may be aware of the loss of half his visual field, is as unconscious of any scotoma as a healthy person is of his blind spot.

W. Harris[5] reported a case of hemianopsia where the patient was aware of no defect of vision whatever, but in which the lesion was in the posterior limb of the internal capsule.

In that some individuals are either vain or extremely sensitive as to their personal appearance we may find a solution, but it seems hardly probable that they could maintain the complete and constant ignorance shown by Babinski's cases. The occurrence of psychical phenomena such as emotionalism, changes of personality, hysteria, and functional motor amnesia with hemiplegia need hardly be mentioned.

Anosognosia has as yet not been observed in men but only in women of whom the mental complex is essentially different from that of men and among whom functional disturbances are most common; however, this does not preclude the possibility of an occurrence in men.

It appears that in anosognosia we are dealing with the condition described by Janet as a dissociation of personality, or if I may be pardoned for quoting, it is that state "in which the actor has learned his part and possibly to the suppression of his own personality."

I wish to express my thanks to Drs. Mills, Lloyd, Spiller, and Burr for material used in the preparation of this paper, and to Dr. Spiller for many kind suggestions.

3103 WALNUT STREET

THE X-RAY AS AN IDEAL LOCAL REMEDY FOR ECZEMA.

BY I. WILLIS BALLARD, M.D.,

OPELIKA, ALA.

THE application of the *x*-ray in the local treatment of eczema is an exhibition of sound judgment in applying to the relief of a definite pathological condition a means that directly combats the pathology present.

The *x*-ray is a form of motion similar to light but with many millions more vibrations per second than light. It is itself invisible and does not produce heat, light, or sound, and its presence is shown only by the fluorescence it induces in certain chemical substances.

Practically a tissue is opaque to the *x*-ray as its specific gravity is high, and the greater the atomic weight of a tissue the greater its resistance to the passage of the *x*-ray. As far as our present knowledge goes, these rays travel in perfectly straight lines and upon striking a solid substance through which they cannot pass, they become absorbed. The specific effect of the *x*-ray is exerted at that point at which it is absorbed.

A difference in their capacity for absorption is shown by the different tissues of the body. The degree of penetration of the *x*-ray, that is, the point at which its absorption takes place, depends upon the atomic weight of the tissue, the vacuum of the tube employed, the nearness of the tube to the surface exposed, and the voltage output of the exciting medium. The effects of an individual treatment are dependent upon these factors plus the length of time of the exposure.

Microorganisms present in tissues at that point at which the rays are absorbed are destroyed. The exposure of seed to its influence prevents their germination. Eggs exposed to the *x*-ray will not hatch. Frequent exposure of the ovaries or testes will produce temporary sterility. Upon the surface of the living body, repeated mild exposures at short intervals will produce an erythema followed by a branny desquamation. If the exposures are continued for several weeks there will occur a bronzing of the skin similar to the ordinary tanning from sunburn.

The explanation of the entire range of *x*-ray therapy is summed up in a few words: Repeated exposures to the *x*-ray impair the vitality of all cells situated at that point at which the rays are absorbed. Rapidly growing cells are many times more susceptible to the rays than are normal tissue cells.

The substance of a soft tissue standing prominently above the surrounding surface is perceptibly contracted by exposure to the *x*-ray. Following a series of exposures it has been observed by all having experience with the rays that the skin becomes atrophied, the hair follicles and sweat glands inactive. Pain is relieved to a remarkable extent in inflammatory and malignant conditions, conditions which emphasize the presence of rapidly growing and immature cells.

These facts point strongly to one effect in particular of the *x*-ray, that is, the contraction of cell protoplasm. Such contraction of cell protoplasm can have but one result, viz., local anemia, the sequence of the contraction of vascular tissue. The *x*-ray burn, the most difficult of all burns to heal, is the result of a profound anemia of the involved tissues. The effects of the *x*-ray are inhibition, inhibition of the circulatory and consequently of the nutritive processes.

In eczema is found one of the richest of its several fields of therapeutic employment. Not alone is it here an ideal treatment in that it is cleanly, painless, certain, and reasonably rapid, but it is an example of one of the most sane instances of the application of a remedial measure with a certain definite non-varying action to the relief of a certain definite pathological condition.

Eczema is distinctly a protean disease, protean not alone in its clinical manifestations but also in its causes. Yet all eczemas have certain characteristics in common. Thus all are inflammation of skin, acute, subacute, or chronic. All involve the epidermis, retemucosa or corium, and all appear as an erythema, macules, papules, vesicles, pustules, or fissures.

Its pathology is always a curcumscribed or diffuse hyperemia with dilatation of blood-vessels, congestion, and edema, together with cell infiltration and proliferation. It is exactly such pathology that requires a form of local treatment that will inhibit the congestion and dilatation of blood-vessels, slow down the rapid cell metamorphosis, and soothe by long exposure to a soft tube or stimulate by short exposure to a hard tube. The technique is not difficult. The satisfaction is very great.

FARMERS NATIONAL BANK BUILDING.

RESULTS OF WASSERMANN AND LUETIN TESTS AT THE NAVAL PRISON, PORTSMOUTH, N. H.

BY G. E. THOMAS,

PAST ASSISTANT SURGEON, U. S. NAVY.

DURING the past year a Wassermann test has been made on every prisoner admitted to this prison. Of the 280 tested, 59 gave a history of a primary lesion and in these cases in addition to the Wassermann, a luetin test was done. The results are tabulated as follows:

TABLE I—RESULTS OF BLOOD TESTS IN ALL CASES ADMITTED TO PRISON.

	Cases	WASSERMANN	
		Negative	Positive
Negative history of sore	221	221	0
Positive history of sore	59	49	10
Total	280	270	10

It is interesting to note in Table I that not one of the 221 cases denying the primary lesion gave a positive Wassermann, evidence complimentary to the frankness of the naval prisoner and the specific value of the Wassermann.

Table II—Cases Giving History of Venereal Sore

	Cases	Wassermann		Luetin	
		Neg.	Pos.	Neg.	Pos.
Positive syphilitic history, received treatment	20	15	5	15	5
Negative syphilitic history, received no treatment	39	32	7	36	3

Table III—Comparative Table of 14 Cases Giving a Positive Wassermann or Luetin

Case	Syp. Hist.	Wassermann	Luetin	Primary Lesion	
1	Positive	Plus	Plus		1911
2	Positive	Plus	Plus		1911
3	Positive	Plus-minus	Plus		1906
4	Positive	Minus	Plus		1906
5	Positive	Minus	Plus		1909

Of the 59 cases giving a history of a primary sore twenty received specific treatment and most of this treatment was given while serving in the Navy. Thirty-five per cent. of this number gave a positive reaction to the specific tests.

In Table III it will be seen that of the eight positive luetins all but two gave a positive Wassermann, both of them being late cases. To draw positive conclusions from such a small number as above reported is impossible, but from our little experience, it appears that the luetin test, when positive is strong evidence of the specific nature of the condition. In late cases it is little if any more constant than the Wassermann.

THE SIGNIFICANCE OF ACIDS AND ALKALIES IN THE ORGANIC WORLD.

By D. S. Kanstoroom, M.D.,
Washington, D. C.

Innumerable acids are found in the structure of all vegetable matter. They are ever present as constituents of the cellular and intercellular elements of the vegetable organisms. We find them in the blade of the lowly grass of the meadow and in the leaf of the mighty oak. We find them in the berries growing on the bushes and in the fruit growing on trees. The golden orange is composed of myriads of tiny sacs laden with an acid fluid. The grape is a receptacle containing an acid juice. Acids are omnipresent in every cell of the vegetable world. What is the significance of this wide distribution of acids?

The animal organism on the other hand is characterized by a persistent alkalinity of its cells and cell media. The normal animal cell must have an alkaline cell medium. The blood, the lymph, and internal secretions must all be alkaline in reaction. Why is alkalinity obligatory to the animal cell?

In order to answer the above pertinent questions, I have envolved a theory, which explains the functions of the acids and alkalies in the organic world.

In the scheme of life the animal, vegetable, and inorganic worlds are inseparably linked together in one solid chain, forged by the process of evolution. In the cycle of life the vegetable organism absorbs elements from the inorganic world and builds up compounds necessary for its existence. The animal organism living off the vegetable world uses these compounds for its sustenance. The difference between the animal and the vegetable cell is mainly due to their difference in the scale of evolution. The animal cell standing at the pinacle of organic evolution is endowed with functions lacking in the vegetable cell. While the animal and vegetable cells possess in common the main functions characteristic of life, the animal cell possess one function lacking in the vegetable cell, which really forms the line of demarcation between the animal and vegetable world. That function is the power to initiate, conduct, and store nervous impulses. The animal organism is endowed with a specialized system, composed of cells and fibers, which has the power to initiate, conduct and store nervous energy or the energy of life. The vegetable organism is not possessed of such a specialized system and hence is dependent on the outside for its life energy. It must derive its energy of life from the soil, sun, and atmosphere.

The energy of life of the vegetable world, the nervous energy of the animal world, light, heat, electricity, radiant energy, are all forms of Cosmic Energy. Organic electricity or the energy manifested in the process of life may be rightly compared with inorganic electricity, as both spring from the same fount. The nerve cell, nerve ganglia, and nerve fiber of the animal organism may be rightly compared to an electric battery and electric wire. Only the living electric battery has the power to replenish its energy automatically by proper nourishment.

The vegetable organism, not having a specialized nervous system and depending on the outside for its life energy, must have a medium, which will easily permit outside forms of energy to influence its life. This medium must take the place of the fibers of the nervous system of the animal organism and must be a good conductor electricity. Such a medium the vegetable organism does possess and it is the omnipresent acid in the vegetable structure, which plays the role of the conductor of electricity of life to the vegetable organism. The acids play the role of fluid nerve fibers, or fluid electric wires.

The inorganic electric battery and wires in order to work properly must be properly insulated. The same is true of the living electric batteries and wires of the animal organism. Perfect nerve insulation is the keystone to normal animal cell action and which is attained only through perfect alkalinity of the animal cell media. The function of perfect animal cell alkalinity is to bring about perfect nerve insulation.

Alkalinity of its cell medium is an imperative necessity to the animal organism. How does it obtain and maintain that alkalinity? Physiology teaches us that acids stimulate alkalinity in the animal cell, and as the food of the animal organism is rich in acids, we see the important double role the organic acids play in the scheme of life.

Résumé.—1. By means of the acid the solar and terestial electricity influences the life and growth of the vegetable organism.

2. Vegetable matter being the natural food of the animal organism through the acid contained in it, promotes the alkalinity of the animal cell and cell medium.

3. Alkalinity of the animal cell medium is important on account of the insulation it affords the nervous system.

THE ABDERHALDEN REACTION.

WHEN Abderhalden published his work on the defensive ferments his ideas there elaborated were held to be the most important contribution to the subject of immunity since the appearance of Ehrlich's side chain theory. His work supplied a long-felt want to the medical profession, that is, an easily understood and generally applicable theory whereby many of the mysteries of the infectious diseases might readily be explained. Moreover, the theory had a very practical bearing in diagnosis. The theory was strengthened when, a little later, Vaughan published his work on protein split products. However, as the use of the method became more general, inconsistencies appeared in the reports. These were first explained as due to errors in technique, but persisted even after the workers had acquired expertness. Later many reliable investigators expressed themselves as being very doubtful of the specificity of the reaction and one, after over two years' work, came to the conclusion that every individual at some time in his or her existence, produces in the blood serum a ferment which is capable of digesting placental albumin.

Bronfenbrenner, however, got such excellent results in his tests that he was convinced of the specificity of the reaction and so set about to investigate its nature in an endeavor to reconcile some of the conflicting evidence which had collected. He has not yet completed his work, but has made several observations (*Jour. Exper. Med.* 1915, XXI, 221) which are of the highest importance. Several attempts to show that immune sera contained specific ferments capable of digesting the substrate were without result although, of course, the methods applied were exceedingly crude when compared with the ninhydrin test following dialysis. It then became apparent that the dialysable substances were derived from the serum itself. If the Abderhalden reaction is carried out in the ice-box the result is always negative, that is, digestion does not occur. He, therefore, allowed pregnant serum to stand over placenta in the ice-box. The placental tissue was then removed by centrifugation, and the test carried out on the serum alone at 37° gave a positive result. It became evident that the reaction may be divided into two phases. The first, consisting of a reaction between the immune serum and the substrate, took place at 0°. The second phase, the physical expression of the result of the first phase, *i. e.* digestion, or better autodigestion of the serum, proceeded only at incubator temperature. In this respect the reaction is analogous to other immunity reactions, agglutination, precipitation, etc. Moreover, this digestion occurred in serum which had been treated with kaolin, barium sulphate and starch. These substances are all recognized absorbing agents, and the conclusion was reached that the placental tissue removed by absorption from the immune serum the substance which exercises an antitryptic action. Following the removal of this inhibition, autodigestion takes place due to the presence of a normal ferment. That blood serum may contain a non-specific protease has been definitely proven, and in this connection especially by Jobling, Eggstein, and Petersen (*loc. cit.*, p. 239).

In view of the above findings it becomes necessary to find an explanation of the apparent specificity which the reaction shows, at least occasionally. Bronfenbrenner found that when placental tissue is exposed to pregnant serum it undergoes definite changes, aside from the increased resistance to digestion due to the absorption of antiferment; it becomes "sensitized" so to speak. This "sensitized" placental albumin, when freed from pregnant serum by washing, is later able to bring about a positive Abderhalden reaction in normal serum or even a succession of normal sera. Heated serum retains the property of sensitizing placenta. Bronfenbrenner is still convinced of the specificity of the reaction though it must be admitted that the question is as yet undecided. The fundamental points of Abderhalden's theory therefore seem not to be substantiated. Specific ferments are not developed in the process of immunization and the reaction is quite analogous to other immunity reactions. The practical value of the test, however, may not be seriously affected. It will be remembered that the Wassermann reaction was proven not to be truly specific and yet it retains its great value in diagnosis. So the Abderhalden test, if properly controlled in the light of these observations, may still be of value along certain lines. One of the first things that is necessary is a determination of the conditions in which a protease appears in the human blood. The part that the complement plays in the reaction is another question concerning which there is marked difference of opinion. The results of further researches in this field will be awaited with much interest.

INBREEDING AND CROSSBREEDING.

IT is almost universally agreed that consanguineous marriages are undesirable. Between immediate ancestor and offspring, or between immediate collaterals—brothers and sisters—marriages do violence to all notions of society and are forbidden in civilized communities. When, however, the degree of relationship is more removed than these, the question of the undesirability of union is a much mooted one. Some States forbid the marriage of cousins, of uncle and niece, or of aunt and nephew. Marriage between cousins is especially hazardous when the objectionable familial defect is dominant in both the

contracting parties. A union between them will but emphasize the familial defect—by pure mathematical multiplication. If, however, the familial defect is recessive, latent, or hidden in both of them, union will yet have a tendency to make them the dominant characteristics in their offspring. Indeed, there are often unexpected outcroppings of these defects in generations removed from the immediate contracting ancestors, probably the result of some novel conditions. Inbreeding results in a homogeneity of offspring in which there rises to the surfaces all recessive qualities.

Inbreeding manifests recessive qualities, but never creates them. In a lesser degree the inbreeding for generations within the race or tribe is objectionable, because it is productive of a homogeneity of race in which there rises to the surface all the racial defects. The best results are obtained from mixtures between the tribes and between the families, but not *in* them. On the other hand a stock or family which, in spite of inbreeding, produces a very high quality of offspring must be a stock of great vigor and with defects. In such case marriage of near relations, as cousins, can only emphasize dominant characteristics. Intermarriage is then a question purely of racial and familial integrity—the integrity of the stock. Where the stock is particularly of high quality it is not unlikely that consanguineous marriages are desirable. The difficulty, however, of determining the dominant character of a stock and its freedom from positive defect is at once apparent. If such marriages must be entered into the stock history should be as carefully gone into for evidence of defect as the personal history and physical condition of those contemplating marriage. In districts where consanguineous marriages are common a rather large percentage of defects, such as deafmutism, mental deficiencies, sterility, etc., have been found. There is no one uniformly bad trait, however, for the trait is dependent upon the specific recessive character of the germ plasm of the common ancester.

The usual breeding, crossbreeding, is desirable because there is a tendency in such unions to hide inherent defects under the more dominant characters of the contracting parties, and to have them ultimately destroyed by the reaction, so to say, of the crossing. Unfortunately the tendency is not to exterminate them immediately, and very often these latent recessive characteristics become patent under unfavorable, but yet unknown conditions. On the other hand, to be desirable the crossbreeding must not be between too widely separated races. It should, of course, be within the species—within the race. It is best between the tribes or subraces; and if it must be within the tribe it should be between as widely separated branches as possible. Breeding between widely differing races, however, is productive of mongrel and undesirable types.

ANTISEPTIC PASTES IN THE TREATMENT OF WOUNDS.

A NEW form of strategy in the treatment or rather the preventing of the septic dangers associated with the wounds of war, is suggested by Sir W. Watson Cheyne in his recent Hunterian Oration (*Lancet*, February 27, 1915). The plan of campaign is not simply the application of antiseptics to the wound, according to the Listerian method, as soon after the infliction of the wound as possible, but is an effort to apply the antiseptic agent in such manner that it will have a continuous action on the bacterial invaders, and by its diffusion will follow these into the surrounding tissues and destroy them or inhibit their growth. Ordinary syringing of the wound is not sufficient to disinfect it; the antiseptic must be introduced into the wound and left there to diffuse into the tissues. Watson Cheyne and his associates devised a method of estimating the diffusibility of antiseptics in blood clot and their action on the bacteria contained in it. The antiseptics were incorporated in a base consisting of six parts of lanoline to one part of white wax. The antiseptic base to be tested was placed on the bottom of a Petri dish underneath a slab of nutrient agar, the upper surface of which was painted with an emulsion of bacteria. The diffusibility and activity of the bacteria were judged by observing the growth or absence of growth of the bacteria planted.

The above method of investigation revealed a number of interesting and a few surprising facts. Thus, with a paste containing 6 per cent. iodine no diffusion of this substance occurred, for the bacterial growth was not inhibited on the agar directly over the iodine paste. This finding apparently contradicts the current conception of iodine as an efficient antiseptic and particularly valuable for its penetrating power. Similarly, alcohol had but slight diffusibility. A 10 per cent. paste of the double cyanide of mercury and zinc had no action; oil of turpentine did not inhibit the growth of bacteria; colloidal mercury, selenium, copper, and silver were also devoid of inhibitory effects. In contrast to the above a 20 per cent. paste of carbolic acid or of tricresol diffused rapidly into the nutrient medium and checked the growth of bacteria before they had formed colonies visible under the low power of the microscope.

Similar results were obtained in a series of experiments in which blood clot was used instead of agar. The findings were also confirmed in animal experiments. The method has produced happy results in the few instances in which it was tried in human beings. The present war provides an unusual opportuity of testing this method of antisepsis on a large scale. It is suggested that tricresol or carbolic acid pastes should be tried first in the strength of 20 per cent. The important object is to find some means of averting sepsis in a wound for some hours, or at most a day or two, until thorough disinfection can be carried out.

THE WIDAL TEST AND ANTITYPHOID INOCULATION.

IN civil practice the Widal reaction is very largely employed in the diagnosis of typhoid fever, yet it is not an infallible indication. When it is negative, the presence of the disease is not excluded, and the reaction may eventually become positive. It is sometimes positive in bacilli carriers, and has appeared

paradoxically in other infections, the subjects of which may have been carriers. The behavior of the reaction in inoculated soldiers and nurses is therefore a matter of great interest. The dead cultures produce, or are believed to produce, antibodies identical with those which form in the disease; so that a Widal positive ought to occur. As a matter of fact, this is what occurs in practically all who have been inoculated. In the *Berliner klinische Wochenschrift* for January 18, Dünner reports a series of over 100 Widal tests in inoculated troops. In the few exceptions in which the Widal was negative it is extremely probable that the soldiers had been inoculated against cholera. Seven inoculated soldiers developed clinical or bacteriological typhoid fever, this number naturally including the carriers; while in one or two of the seven soldiers there was some uncertainty as to whether the inoculation had not been against cholera. Of 97 other inoculated soldiers with the same exposure, not one developed tphoid.

A New Bacterial Disease of Rodents.

Three years ago Dr. G. W. McCoy met with a disease of California ground squirrels which somewhat closely simulated plague, and reported it in Public Health Bulletin No. 48, 1911. Later Drs. McCoy and Chas. W. Chapin published further observations in the *Journal of Infectious Diseases*, 1912, p. 61, and described the *Bacterium tularense*, which they isolated and proved to be the cause of this disease. Dr. William B. Wherry and Dr. B. H. Lamb subsequently discovered two cases of human infection with *B. tularense* in Cincinnati. The first of the cases was reporated in detail in the *Journal of Infectious Diseases*, 1914, p. 331. Another case not yet reported has come under the care of Dr. Robert Sattler. Dr. Wherry, writing in the U. S. Public Health Reports of Dec. 18, 1914, says that the source of infection was found to be wild rabbits from Indiana and Kentucky, and he and Dr. Lamb are inclined to conclude that this rodent disease is widely distributed and that extensive epizootics among wild rabbits occur frequently. It should be said that both cases of infection of the human subject were in the form of conjunctivitis, but it seems possible that other types of infection in man may occur. It is also suggested that rodent fleas may possibly transmit the disease to man, as McCoy and Chapin, in searching for a natural mode of transmission among ground squirrels, twice successfully transmitted the disease by means of squirrel fleas.

War Psychoses.

Much has been written on this subject since the outbreak of the present war, but after all nothing has been unearthed in this relation which has not always obtained in connection with warfare and other catastrophes, like earthquakes. At a recent (January 2) session of the military medical evenings of the Fifth Army (*Muenchener medizinische Wochenschrift*, February 9), Singer spoke as follows: "Nearly all soldiers who 'become insane' in wartime are already mentally ill when enrolled. Psycopaths, hystericals—even manic-depressives—get into the ranks. Certain elements work on the psyche at a later date—enthusiasm, rumors, spy fear, etc. The hardships of war cause in psychopathic personalities depressions, neurasthenia, amentia, acute hallucinations. The prognosis here is good. With certain predisposition, shell fire will call forth a fright psychosis. Abstinence from alcohol exerts a favorable influence over war psychoses, and conversely small doses of alcohol in warfare act in excess and cause delirium, convulsions, etc." In discussion Weyert emphasized the fact that in warfare neurasthenics suffer especially from homesickness. Contrariwise the effects of war on some of the subjects have been pronounced salutary by the same author. Von Hecker believes that warfare accelerates the course of paresis.

News of the Week.

For Belgian Relief.—Statistics concerning the relief afforded the inhabitants of Belgium up to the end of the month of January give the total of contributions of money and provisions as follows: From the United States, $6,200,000; from Great Britain, $920,000; from New Zealand, $500,000; from Australia, $500,000; from Canada, $800,000, and from Spain and Italy, $20,000 each. Belgian banks and mercantile institutions have contributed $10,000,000, in addition to $3,000,000 to the commission's transportation fund.

In a recent address Mr. Lindon W. Bates, Vice-Chairman of the Commission for Relief in Belgium, said: "The Commission was granted by the German Government not only the sole right to transport food into Belgium but given the active sympathy and aid of the German military authorities. Despite reports to the contrary, not one pound of food sent in has been appropriated. The treasury of the Commission draws from the generous heart of the world. Into this treasury has been put also all that the enveloped Belgian race could gather of the remnants of their shattered fortunes. It registers their struggle for survival. It represents their very all —the all that the better-to-do can give to help themselves and unreservedly to help their fellow beings in the ranks already destitute and starving. This is our main purchasing fund—the greatest and the sacredest of all the donations." The commission has landed sixty shiploads of food, worth $21,592,995, in Belgium. The contributions made by American doctors, through the Committee of American Physicians for the Aid of the Belgian Profession, are placed in the hands of the Commission for distribution among the members of the Belgian profession and their families. Mr. Brand Whitlock, American Minister at Brussels, is credited with saying on March 17, that the food then in Belgium would not last longer than April 1.

The Treasurer of the Committee of American Physicians for the Aid of the Belgium Profession, reports the following contributions received during the week ending March 20, 1915:

Sebastian Co. Medical Society, Fort Smith, Ark.	$15.00
Dr. F. W. Johnson, Boston, Mass.	25.00
Dr. E. P. Quain, Bismarck, N. Dak.	10.00
Dr. N. O. Ramstad, Bismarck, N. Dak.	10.00
Dr. Haven Emerson, New York, N. Y.	15.00
Dr. Edward B. Angell, Rochester, N. Y.	10.00
Dr. T. A. Davis, Chicago, Ill.	25.00
New Bedford Medical Society, New Bedford, Mass.	50.00
Dr. Newton B. Waller, New York, N. Y.	5.00
Dr. Charles G. Eicher, McKees Rocks, Pa.	5.00
Dr. William H. Perry, Sterling, Ill.	5.00
Dr. Frederick A. Stafford, Flandreau, S. Dak.	10.00
Dr. George L. Johnson, Newfolden, Minn.	1.00
Salt Lake Co. Med. Soc., Salt Lake City, Utah.	100.50
Dr. and Mrs. Clem D. McCoy, Kenton, Ohio.	50.00
Dr. E. A. Weiss, Pittsburgh, Pa.	10.00
Dr. Hubert Claytor, Hopkins, S. C.	5.00
Dr. C. E. Goodman, Virginia, Minn.	5.00
Tri-County Medical Society, Copiah-Lincoln-Pike Counties, Miss.	10.00
Dr. Harold W. Dana, Boston, Mass.	25.00
Receipts for the week ending March 20.	$391.50

Previously reported receipts		4,830.00
Total receipts		$5,221.50
Previously reported disbursements.		
1,625 standard boxes of food at $2.20.	$3,575.00	
542 standard boxes of food at $2.30....	1,246.60	
Disbursements for the week ending Mar. 20,		
173 standard boxes of food at $2.30.....	397.90	
Total disbursements		5,219.50
Balance		$2.00

To Fight Serbian Typhus.—The American Red Cross is sending a sanitary commission to Serbia to aid in repressing the epidemics of typhus, typhoid, and cholera which threaten to work greater disaster in that afflicted country than all the armed forces of Austria. At the head of the commission will be Dr. Richard P. Strong of Harvard, and the further personnel is as follows: Chief sanitary inspector, Dr. Thomas W. Jackson of Philadelphia; bacteriologist, Dr. Hans Zinsser, professor of bacteriology, Columbia University; clinical laboratory assistant, Dr. Andrew W. Sellards of Harvard Medical School; clinical assistant, Dr. George C. Shattuck of Harvard Medical School; assistant sanitary inspector, Dr. Francis B. Grinnell of Harvard Medical School. Dr. Nicolle, the French expert on typhus, has been invited to cooperate with the commission, and Dr. George Converse of San Francisco and Messrs. Della Pena and Standifer, assistant sanitary inspectors in the Canal Zone, will also join it.

Red Cross Unit for Russia.—Dr. H. H. Snively of Columbus, Ohio, and ten graduate nurses sailed on the steamship *Bergensfjord* last week en route for Russia to join the American Red Cross workers in the army of that country.

A Harvard Unit for the American Ambulance Hospital.—On March 17 a number of graduates of the Harvard Medical School sailed on the *Canopic* to enter the service of the American Ambulance Hospital at Neuilly, Paris. The head of the unit is Dr. Harvey Cushing, assisted by Dr. Robert B. Greenough, and other members are Drs. Robert B. Osgood, Beth Vincent, Walter M. Boothby, Fred A. Coller, Elliot C. Cutler, Philip D. Wilson, Marius N. Smith-Peterson, Lyman G. Barton, Jr., Orville F. Rogers, Jr., and George Benet.

The Death Rate in New York City during the week ending March 13 was 1 1/3 points lower than during the corresponding week of 1914. Comparison of the figures for the week with those of the corresponding week of 1914 reveals a considerably decreased mortality for nearly all causes of death with the exception of the degenerative diseases, organic heart and kidney diseases, in which the death rate was approximately the same. The death rate so far this year, namely 13.95, is considerably below that of the corresponding period in 1914, there being a decrease in the rate of 1.5 points.

The Passing of the Coroners.—The Senate Cities Committee of the New York Legislature voted last week to report favorably the bill of Senator Cromwell of Richmond abolishing the offices of Coroners of New York county and providing for the appointment by the Mayor of a chief medical examiner to perform their duties. The medical examiner is empowered to name his assistants and such other employees as he desires.

A New Post-Graduate School in Chicago.—Announcement is made of the opening in the near future of a new institution to be known as the Graduate School of Medicine of Chicago. Post-graduate instruction will be free to physicians resident in Cook county, while outside physician students will pay fees in support of the school. Affiliated with the school will be a number of hospitals and laboratories of Chicago.

Penalties for Failure to Report Births.—Some time ago the Health Department of this city undertook a survey to discover how completely physicians and midwives were reporting the births occurring in their practice. The survey showed that nearly all the births were being promptly reported as required by law. This result, however, has been attained only through constant vigilance on the part of the Registrar and not without prompt legal action by the department for the imposition of penalties on those disobeying the law. The following summary of penalties imposed since September 1, 1914, shows what may be expected by those who are delinquent in this important matter: 36 physicians paid $10 each, it being their first offence; 12 midwives paid from $1 to $5 each, it being their first offence; 6 physicians paid from $10 to $100 each, it being their second offence; 1 person paid a penalty of $10 for submitting a false affidavit in connection with a birth certificate.

The Panama Exposition Hospital.—The Exposition Hospital is a working exhibit. It is under the able management of Dr. R. M. Woodward of the United States Public Health Service. On his staff are: Dr. L. O. Weldon, Dr. Walter M. Jones, Dr. H. H. Dignan, Dr. Charles N. Leach. There are nurses, orderlies, motor ambulances, and emergency stations at various parts of the grounds to render immediate first aid service. The Emergency Hospital and equipment reflect great credit on Surgeon-General Blue of the Public Health Service of the United States.—*Pacific Medical Journal.*

Proposed Change in the New York State Hospital Commission.—The Senate Finance Committee of the New York Legislature last week reported out the Sage bill intended to substitute a single-headed hospital department for the present Hospital Commission. The bill would legislate out of office Andrew D. Morgan or Ilion, Dr. James V. May of Binghamton, and Fred H. Parker of Esopus, the present Commissioners.

Dr. Herbert M. Smith of Columbia has been elected sanitary physician for Richland County, S. C., by the executive committee of the State Board of Health.

Dr. John N. Hurty, Indiana State Health Commissioner, was the guest of honor at a dinner in Indianapolis on March 13, to commemorate his twentieth year of consecutive service for the State.

The Society of American Bacteriologists.—The Council of this society has decided to hold a special summer meeting in San Francisco, August 3, 4, and 5, 1915. The chairman of the local committee of arrangements is Dr. Wilfred H. Manwaring, Stanford University, California.

The Texas Surgical Society was organized at Houston on March 6 at a meeting of a number of the prominent surgeons of the State. Dr. James E. Thompson of Galveston was elected president, and Dr. W. Burton Thorning of Houston, secretary. The new society announced as one of the objects of its establishment the abolition of the practice of fee-splitting.

The Rockefeller Sanitary Commission was succeeded on January 1 by the International Health Commission of the Rockefeller Foundation, and on April 1 the headquarters of the Commission will be removed from Washington to 61 Broadway, New York City.

Charitable Bequests.—By the will of the late Elizabeth S. Scattergood of Philadelphia the sum of $5,000 is bequeathed to the Hahnemann Hospital for the endowment of a bed in the children's ward as a memorial to Mary Phipps Scattergood, a daughter, and also the sum of $5,000 to endow two beds in the same institution in the women's medical and men's medical wards respectively. The residue of the estate is bequeathed to the Hospital for Diseases of the Lungs at Chestnut Hill.

Mortality in the German Army Medical Corps.—A report from Copenhagen on March 15 says the German casualty lists show that 119 German surgeons have been killed, 235 wounded, and 95 are missing.

Deaths of Foreign Medical Men.—Sir George Turner died at Colyton, Devon, of leprosy on March 12. He was born in Melbourne in 1851 and contracted the disease which killed him while studying it in South Africa. He was knighted in recognition of this work.

Dr. Theodor Grödel of Bad Nauheim died early in February. He was a medical officer of renown in the German Army.

Dr. Karel Pawlik, the well-known obstetrician and gynecologist of Prague, is dead. He was born in 1849.

Professor Stanislas von Prowazek, who was the successor of Schaudinn at the Institut für Schiffs- und Tropenkrankheiten in Hamburg, died on March 17 of typhus fever.

Medical Society Elections.—The Johnson County (Mo.) Medical Society, at its annual meeting held in Tecumseh on January 21, elected the following officers: *President*, Dr. G. W. Townley; *Vice-President*, Dr. D. M. Judkins; *Secretary-Treasurer*, Dr. T. E. Fairall; *Censor*, Dr. C. W. Davies; *Delegate to State Convention*, Dr. M. Stewart; *Alternate*, Dr. C. D. Barnes.

The Piscataquis (Me.) Medical Association, at its annual meeting, held January 21, elected the following officers: *President*, Dr. C. C. Hall; *Vice-President*, Dr. Edgar T. Flint; *Secretary and Treasurer*, Dr. G. E. Dore, Guilford; *Member Legislative Committee*, Dr. E. D. Merrill; *Delegate to the Maine Medical Association*, Dr. R. H. Marsh, Guilford.

The Fort Madison (Iowa) Medical Society, at its annual meeting on January 25, elected the following officers: *President*, Dr. W. C. Kasten; *Vice-President*, Dr. M. L. Bishoff; *Secretary and Treasurer*, Dr. W. H. Newlon.

The Aberdeen District (S. D.) Medical Society, at a meeting held January 26, elected the following officers: *President*, Dr. H. I. King, Aberdeen; *Vice-President*, Dr. Percy Peabody, Webster; *Secretary*, Dr. Carson Murdy, Aberdeen; *Treasurer*, Dr. J. E. Bruner, Frederick.

The Westerly (R. I.) Physicians' Association, at the annual meeting held February 4, elected the following officers: *President*, Dr. F. I. Payne; *Vice-President*, Dr. Charles P. Crandall; *Secretary*, Dr. W. A. Hillard; *Treasurer*, Dr. John Champlin; *Censor*, Dr. Samuel C. Webster.

The San Francisco County (Cal.) Medical Society has elected the following officers for the year 1915: *President*, Dr. H. C. Moffit; *First Vice-President*, Dr. George E. Ebright; *Second Vice-President*, Dr. Cullen F. Welty; *Secretary-Treasurer*, Dr. Rene Bine; *Librarian*, Dr. Leo Eloesser.

The Philadelphia Medico-Legal Society, at its meeting held January 26, elected the following officers: *President*, Dr. Ernest W. Kelsey; *First Vice-President*, Dr. James H. White; *Second Vice-President*, Dr. John Strobel; *Secretary*, Dr. Charles W. Schauble; *Treasurer*, Dr. G. M. D. Peltz; *Censors*, Drs. G. C. Yeager, John H. Dripps, and Lambert Ott.

The North Idaho District Medical Society, at a meeting held in Lewiston, January 20, elected the following officers: *President*, Dr. E. G. Braddock; *Secretary-Treasurer*, Dr. A. M. Frank. The next meeting will be held in Moscow.

Obituary Notes.—Dr. Waldron Burritt Vanderpoel of New York, a graduate of the College of Physicians and Surgeons, New York, in 1879, and a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Association of the Alumni of the College of Physicians and Surgeons, and the Alumni of Bellevue Hospital, died at his home in Summit, N. J., on March 9, aged 60 years.

Dr. Stuart Harry Benton of Brooklyn, N. Y., a graduate of the University of Buffalo, Medical Department, in 1870, and a member of the Associated Physicians of Long Island, died at his home on March 2, aged 69 years.

Dr. Albert Simon Newcomb of Schenectady, N. Y., a graduate of the Albany Medical College in 1860, formerly medical examiner for the New York Post Office, died at his home on March 1, aged 74 years.

Dr. Henry Lambard Nichols of Sacramento, Cal., a graduate of the Medical School of Maine, Portland, in 1845, Secretary of State for California from 1867 to 1871, formerly president of the county board of supervisors and city health officer, and a member of the American Medical Association, the Medical Society of the State of California, and the Sacramento County Medical Society, died at his home, after a brief illness, on February 16, aged 91 years.

Dr. Walter Montgomery James of Philadelphia, a graduate of the Homeopathic Medical College of Pennsylvania, Philadelphia, in 1869, founder and for many years editor of the *Homeopathic Physicians' Journal*, and a member of the Germantown Homeopathic Club, died at his home, after a long illness, on February 24, aged 65 years.

Dr. Henry Cutler Baldwin of Boston, Mass., a graduate of the Harvard University Medical School in 1884, chief of the neurological department of the Massachusetts General Hospital, and a member of the American Medical Association, the Massachusetts Medical Society, the American Neurological Association, the Boston Society of Psychiatry and Neurology, the Alumni Associations of the Harvard Medical School and the Massachusetts General Hospital, and the American Medico-Psychological Association, died at the Massachusetts General Hospital, after a brief illness, on February 25, aged 55 years.

Dr. Gustavus Judson Nelson of China, Me., a graduate of the Medical School of Maine, Portland, in 1877, for fifteen years superintendent of the public schools in China and for thirteen years secretary of the Board of Health, died at his home on February 19, aged 69 years.

Dr. Fred W. A. Brown of Oshkosh, Wis., a graduate of McGill University, Medical Faculty, Montreal, in 1892, and a member of the American Medical Association, the State Medical Society of Wisconsin, and the Winnebago County Medical Society, died suddenly, from neuralgia of the heart, on February 20, aged 52 years.

Dr. Charles A. Scribner of Louisville, Ky., a graduate of the Kentucky University, Medical Department, Louisville, in 1906, died at the home of his brother in Bloomington, Ill., after a lingering illness, on February 19, aged 56 years.

Dr. P. N. Richardson of Jacksonville, Fla., a graduate of the Meharry Medical College, Nashville, Tenn., in 1892, died at his home after a short illness on February 18.

Dr. Frank Dean Bain of Kenton, O., a graduate of the Bellevue Hospital Medical College, New York, in 1872, a surgeon of the Second Regiment, Ohio Volunteer Infantry, during the Spanish-American War, and a member of the American Medical Association, the Ohio State Medical Association, and the Hardin County Medical Society, died at his home, from neuralgia of the heart, on February 22.

Dr. Paul E. Trees of Maxwell, Ind., a graduate of the Medical College of Indiana, Indianapolis, in 1905, and a member of the Indiana State Medical Association and the Hancock County Medical Society, being in his second term as president of the latter, died at his home, following an operation performed a week before, on February 19, aged 35 years.

Dr. James S. Herron of Pensacola, Fla., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1861, a surgeon in the Confederate Army during the Civil War, and acting assistant surgeon in the United States Army during the yellow fever epidemics of 1873 and 1875, died at his home on February 20, aged 79 years.

Dr. A. Judson Collar of Yreka, Cal., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1884, died at the home of his son in Alameda, Cal., on February 21.

Dr. Thomas C. Doolin of Ash Grove, Mo., a graduate of the Washington University Medical School, St. Louis, in 1911, died suddenly on February 20, as the result of an accident.

Dr. E. L. Tillinghast of Mooringsport, La., a graduate of the Tulane University of Louisiana, School of Medicine, New Orleans, in 1861, died at his home after a brief illness on February 23.

Dr. Colbert Hanchett Cannon of Eugene, Ore., a graduate of the National Medical University, Chicago, in 1905, and of the Hering Medical College, Chicago, in 1906, and a member of the Oregon State Medical Association and the Medical Society of Lane County, died at his home after a long illness on February 18, aged 68 years.

Dr. Thomas Byrne of West Hoboken, N. J., a graduate of the New York University Medical College, in 1888, and surgeon to the North Hudson County Hospital, Weehawken, died at his home on March 2.

Dr. Henry Hersch Hart of San Francisco, Cal., a graduate of the Cooper Medical College, San Francisco, in 1879, and a member of the Medical Society of the State of California and the San Francisco Medical Society, died suddenly, while assisting at an operation on March 5, aged 61 years.

Dr. Curtiss Clark Hoyt of Bridgeport, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1887, formerly city physician of Bridgeport and president of the Board of Health, and a member of the Connecticut State and Fairfield County Medical Societies, died suddenly at his home on February 5, aged 62 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE HUNTERIAN ORATION—WOUNDS IN WAR—FROST-BITE—UNILATERAL OVARIAN TUMORS—OBITUARY.

London, March 5, 1915.

Sir Watson Cheyne delivered the Hunterian oration this year and remarked that he had not read the sixty-seven others that have been given since the death of John Hunter nearly 122 years ago, but while considering what in his scheme of life and disease might be interesting at the present time, he fell in with the wishes of some colleagues to devote his lecture to the treatment of wounds in war. And many will be glad that he did so for he has treated it in a most interesting way. Speaking of it as a puzzle which is still unsolved though it has "exercised the minds of medical men since the world began" (perhaps he means the medical world), he says Hunter was always trying to solve puzzles and weaving theories to explain them or modifying or adding to them as became necessary. So, too, he said the attempt to solve this one is a matter of common gratitude to those brave men who risk their lives for us.

Hunter had some slight experience of war and wrote an article on gunshot wounds—still interesting. His service for a time in the army seems to have been the foundation of his great museum for he brought home some 200 specimens he had collected.

Though he realizes the difficulties of thoroughly disinfecting wounds in war, he is far from regarding them with the hopelessness of some surgeons. We have no doubts on the matter in civil practice—why then despair about it in war? He formed a small committee with Fleet-Surgeon Bassett-Smith and Mr. Arthur Edmunds to investigate and acknowledges the help they received from the Director-General (Sir A. May) and the staff of the Royal Naval Hospital. They set to work to find out if it were possible to introduce an antiseptic into a wound soon after infliction which would remain there, diffuse in the blood and tissues, and inhibit the growth of the bacteria until such time as the wound could be thoroughly disinfected. To work out this problem they had to estimate the diffusibility of antiseptics in blood-clot and their action on bacteria in or on that clot and they soon found that it varied with the medium conveying them, the antiseptics used, and their strength, with other circumstances. The results differ with the base combined with the antiseptic, and he showed a series of 20 per cent. carbolic pastes in five bases. The greatest diffusion was obtained with pure lanoline—the least with paraffin, this latter being only half that of the former. But the lanoline combination is too diffluent and too pungent. The addition of wax lessens the activity about a quarter and does not irritate the skin, so a little more can be used to get the full effect. Some interesting experiments had been made to imitate the conditions of a wound inflicted in war. Cresol ointment and other pastes were used to test the vitality of bacteria and spores. It was found that a number of substances can penetrate agar or blood-clot to a depth of $\frac{1}{4}$ or $\frac{1}{2}$ inch and still retain sufficient antiseptic power to prevent the growth of organisms and this penetration takes less than three hours. On man a single dressing with such pastes prevented infection for four days. In

another case of a very dirty wound, much tissue bordering on the wound being actually dead, no suppuration, no sign of infection was seen for ten days. From the facts stated it would appear that an advance may be arrested in the treatment of wounds in war, for the danger which arises from the delay in getting the wounded from the front to the base is so far removed. The arrest of sepsis will be the more certain, the sooner the antiseptic can be applied. The problem therefore is to apply it the earliest moment after the infliction of the wound and that must be at the front.

A paper on frost-bite or the condition so-called seems a timeous production just now and the Royal Society of Medicine has been favored with one by Mr. R. H. Jocelyn Swan, based on 100 cases among soldiers returned from the front. Of these eighty have been treated by him in the Herbert Hospital, the common causal condition—and indeed the only one—being standing a long time with wet feet. He found two distinct groups of cases. In one (*a*) there was only slight destruction of tissue, but there were marked subjective symptoms; in the other (*b*) gangrene was present in various degrees, from a superficial skin lesion to one in which there was a destruction of one or more of the toes. In group (*a*) cutaneous anesthesia and analgesia would often be observed—shown in the loss of the joint sense and the sense of vibration; sometimes an opposite condition prevailed—seen in a patchy hyperesthesia with pain on movement or pressure. Mr. Swan did not look upon the state as a neurosis which some considered it to be. He rather regarded it as the consequence of some change in the processes of nutrition, as to the more serious cases gangrene was often worst in the great toe and the majority of cases were examples of dry gangrene. It was usually one foot that was affected though there seemed to be no reason for this—it certainly had no relation to points of pressure. Mr. Swan suggested that the condition might, perhaps, be attributed to the combination of wet feet with want of exercise in the dependent position, rather than to intensity of cold. Canadian officers had told him that true frostbite seemed different. He suggested as a preventive wearing a thin covering of mackintosh over the sock, but inside the puttee; also the free use of vaseline or whale oil to protect against the wet. The boots, too, ought to be large enough to allow free movement of the toes.

Dr. Galloway considered the affection a thrombotic phleboarteritis obliterans. Dr. Fearnsides described three varieties of cases: (1) Those with objective signs and perhaps some sensory loss, but without any subjective symptoms; (2) an intermediate class with slight alteration of sensation—a blunting, not amounting to anesthesia, with a band of hyperesthesia at the upper border of the affected area; (3) those in which sensation was lost over an area of the stocking type, which in ordinary civil practice would be ascribed to neurosis.

He said that in the Balkan war they had agreed that the objective changes were vascular in origin.

In the Section of Gynecology the question came forward of the nature of the unilateral soft, solid, ovarian tumors. Dr. Herbert Spencer read notes of a case which had ruptured in a patient aged 27. It measured $5\frac{3}{4}$ by $3\frac{1}{2}$ inches and there was about a gallon of blood-stained fluid in the peritoneum. Removal was successful, the patient continued well for seven years and had two children. Microscopically the tumor seemed a medullary sarcoma, but notwithstanding Dr. Spencer admitted it might possibly be non-malignant. Dr. Lockyer was not satisfied that it was a carcinoma but perhaps an endothelioma which was much less malignant in the ovary. Dr. Spencer did not agree with Pfannenstiel that in all cases of unilateral cancer and endothelioma of the ovary both ovaries should be removed for he had seen cases remain well for seven years after unilateral ovariotomy. Dr. Henry Briggs had catalogued them for years as solid adenomata awaiting further advance in histology. Dr. Spencer replying to other remarks said he would treat a similar case in the same way; it was difficult to cut satisfactory sections at the time of operation; he had not decided whether the tumor was malignant or not; the other ovary looked normal and was not removed; if it subsequently grew he would remove it but with very little hope that malignant disease of both ovaries would not recur.

Lt.-Col. Malcolm Albert Ker, I.M.S., has died in London at the age of 53. He qualified at Edinburgh in 1884 and joined the Indian (Bengal) Medical Service in 1887. He took part in the Hazara Expedition 1888-91, the Second Maranzai Expedition 1891, the Waziristan 1894-5, the Tirah campaign 1897, and the Waziristan campaign 1901-2.

5. A Study of the Efficiency of Mixed Toxins (Coley) in Inoperable Sarcoma. A Critical Analysis of 134 Microscopically-Proven Cases. T. W. Harmer.

1. Superstition and the Doctor.—Owen Wister shows how from the time of the pyramids to the present the human race has not changed much. Superstition is still rife. In 1911 in the United States $77,000,000 were paid to get-rich-quick fakirs, subsequently convicted of fraudulent use of the mails. The ℞ at the beginning of the doctor's prescription is the crumbled remnant of the symbol of Jupiter: astrology still keeps the tip of her finger in the pie. In the beginning of civilization the physician was combined in the same person with the statesman and the priest; in the course of evolution he separated himself from the priest and became secular. Then, in curious analogy to the archaic specialization of gods presiding over various portions of the human frame, the doctor in his turn has specialized, so that to-day he is divided into many fragments, one for the eyes, another for the ears and throat, and so on; yet, sigularly enough, as civilization grows increasingly complex, the doctor's path is leading him again toward a union or cooperation with the Church and the State. Once more, as of old, his duty to the community tends to come before his duty to the individual, because one is beginning to see the community's health as a unit.

2. Diverticulum of the Bladder.—H. Cabot emphasizes the following important points in the operative treatment of this condition: Free bladder incisions carried down to the orifice of the sac in the more accessible cases, the opening of the ureter and the placing of a guide bougie in all cases in which the diverticulum is in the neighborhood of a ureteral orifice; and finally, the constant drainage of the ureter for some days in those cases in which resection has been necessary or the flap operation of Young has been possible.

3. **Splenic Anemia.**—P. E. Truesdale reports a case of this condition in a woman aged 21 years. There was a close clinical analogy to gastric ulcer. The patient had a persistent disturbance of digestion, hunger between meals, intermittent attacks of hematemesis, and epigastric tenderness. During one attack examination revealed an elevation of temperature and pulse associated with a distention and a marked tenderness over the upper abdomen. These symptoms were explained by the presence in the upper surface of the spleen of a large area that had become necrotic. Later, when an enlargement of the spleen was detected, a blood examination was made and revealed the diagnosis. Splenic anemia occurs in young adults as a rule. It begins insidiously and at first progresses slowly. The first indication may be hematemesis, epistaxis, and a melena, slight or so severe as to be almost fatal. Senator states that the blood examination reveals a fairly uniform condition. There are a diminution in the red blood cells, a low percentage of hemoglobin, and a leucopenia. In the later stages of the disease ascites appears, preceded or not by cirrhosis of the liver. It is this association of enlarged spleen, ascites, and cirrhosis of the liver to which Banti has drawn special attention. He pointed out that in cases of this association the enlargement of the spleen, sometimes at least, was the precursor of the other two conditions and probably was the original focus.

9. The Nature and Pathogenesis of Epilepsy. L. Pierce Clark.

1. **Treatment of Mental Affections in General Practice.**—F. X. Dercum notes that among the most common mental disturbances met with by the practitioner is the delirium accompanying the ordinary infectious diseases. The treatment follows three indications: First, the elimination of the poison; secondly, the maintenance of the strength, and, thirdly, the allaying of the excitement as far as may be necessary. The means at one's command consist in the free administration of water, the free use of baths, the free administration of nourishment, and the administration, when necessary, of cardiac stimulants and sedatives. Sometimes sponge bathing in bed is applicable; the most efficient form of bath is the prolonged warm immersion bath, at 90 or 95° F. If the delirium is violent and persistent one may give a hypodermic injection of scopolamine, 1/200 grain and morphine 1/16 grain. In alcoholic delirium a full dose of paraldehyde is effective. Stuporous states supervening upon the infectious diseases demand a similar treatment. One should avoid the mistakes of confounding a delirium with a mania. A delirium has a duration of a few hours or a few days, while a mania has a duration of several months. The excitement of mania differs from that of delirium in the absence of confusion and hallucinations, and in the fact that delusions form no feature of the picture. In practice melancholia is the only member of the manic depressive group which can be successfully treated outside of institutions, and this only when the melancholia is mild in degree and under special circumstances. In the extramural treatment of melancholia the best results are secured by full rest methods, such as are carried out in the treatment of neurasthenia. The tendency to suicide must be specially guarded against. Cases of dementia præcox are, as a rule, of such a character as to necessitate asylum commitment, nor are paranoia and paranoid cases generally suitable for extramural treatment. One is rarely justified in committing to the asylum cases of psychasthenia. Many of these patients present evidences of hypothyroidism. The author emphasizes the importance of simple physiological procedures such as rest and full feeding.

4. **X-Ray Prevention of Nasal Diseases.**—S. Tousey states that it often happens that a set of permanent teeth develop in a jaw which is not nearly wide enough to accommodate them. The most obvious result is that the permanent teeth are variously malpositioned and delayed in eruption. But of more vital consequence is the interference with the development of the superior maxillary bones. The hard palate has a narrower base than natural and is pushed up into an unnaturally high arch. This presses up the nasal septum, then in a cartilaginous or formative state, and crumples it into spurs and deviations, which in later life are bony and cause a train of symptoms and operations. The young child has mouth breathing not entirely relieved by surgical treatment of the adenoids and hypertrophied tonsils. *X*-ray examination at the age of five or six years enables one accurately to measure the size of the oncoming permanent teeth and to determine beforehand the curvature of the jaw required for their natural development. With this information it is an easy matter for the dentist to regulate the temporary teeth to such a curve as is required to guide the natural development of the permanent teeth. The calculation of the proper curve is part of the work of the radiographer, but the orthodontist will take into consideration, not only the size that he is told the permanent teeth are to have, but also the type of face in which these teeth are to develop. The *X*-ray measurement will frequently show that nature has provided the proper curve, and this knowledge may save the child from harmful efforts at regulating the temporary teeth when they do not require it.

10. The Treatment of Psoriasis with Vaccines. E. D. Holland

2. **Reversal of the Circulation.**—J. Shelton Horsley and R. H. Whitehead have performed on dogs the operation of reversing the circulation in the lower extremity — that is, attaching the cardiac end of the artery to the distal end of the vein, and the distal end of the artery to the cardiac end of the vein, which operation had been reported as possible in dogs by Carrel and Guthrie, but which had been considered as of little actual value by Halsted and Vaughan. The authors conclude that the operation has no legitimate place in clinical surgery except possibly in Raynaud's disease, if one accepts this solely as a spasm of the arterioles. It seems unjustifiable in gangrene due to

organic disease of the artery, in which the operation of ligating the femoral vein seems more suitable.

4. Boric Acid in Skin Diseases.—D. W. Montgomery makes an extensive use of boric acid, as an adjuvant to other remedies, in diseases of the skin. Besides its mild and non-irritant antiseptic property, it is soothing. The diseases in which it is useful are acne, in which soaking with a hot boric acid solution is often of great benefit; pyrogenic infection of the skin; furuncles, especially styes; impetigo contagiosa, in which a boric acid and starch poultice is one of the best applications for the first treatment, the crust being removed with an ointment composed of 15 parts of ammoniated mercurial ointment, and 30 parts of zinc oxide ointment; perleche (streptococcic infection of the corners of the mouth); runarounds; and various discharging diseases of the skin.

5. Tubercle Bacilli in the Urine.—Lawrason Brown concludes that no staining method differentiates absolutely tubercle bacilli from smegma bacilli, but cultural methods may aid greatly. Animal inoculation, with the production of tuberculosis, is an absolute test, but of value only when positive. The same care about the collection of urine should be exercised as about the collection of sputum. Tubercle bacilli can be excreted through apparently normal kidneys. Radiography may aid in the quick detection of caseous foci when the urine contains no tubercle bacilli. Spontaneous healing is often fictitious. The final, and often the best, treatment for renal tuberculosis on diagnosis, is nephrectomy followed by the use of tuberculin. Tubercle bacilli occur in the urine in genital tuberculosis usually late in the disease and are consequently of little aid in the diagnosis of the condition.

8. Artificial Pneumothorax.—L. S. Mace points out that the most favorable cases for lung compression are those in which cavity formation has not occurred but which, under the usual methods of treatment, are progressing toward softening. In some advanced cases with large cavities, much relief of distressing symptoms may be obtained by compressing the more advanced lung. Removal of fluid with temporary compression by nitrogen gas or air is the most rapid and effective method of treating large pleuritic effusions. Hemorrhage is usually promptly and permanently relieved by artificial pneumothorax. Compression of one lung does not induce increased activity of the disease on the opposite side.

9. Alcohol and the Circulation.—C. C. Lieb concludes from his experiments on cats that even though whisky may raise for a few moments the systolic blood pressure, and thus act as an apparent circulatory stimulant, it can not be regarded as a true circulatory stimulant, inasmuch as it decreases cardiac efficiency, raises disproportionately the diastolic pressure, and lowers the pulse pressure.

1. The Treatment of Wounds in War. Sir W. Watson Cheyne.
2. Colloidal Iodine Associated with Serum Treatment in Tetanus. Dr. Auregan.
3. On Headache Associated with Intranasal Disorders. L. Hemington Pegler, M.D.

1. Treatment of Wounds in War.—By Sir W. Watson Cheyne. (See page 526.)

2. Colloidal Iodine and Serum Treatment in Tetanus.—Dr. Auregan, who has been in charge of a supplementary hospital of 1,100 beds at Lannion, France, has had the opportunity of treating twenty-three cases of tetanus from September to December, 1914. In addition to the serum treatment he has employed local applications of a 20 per cent. oleaginous suspension of electrochemical colloidal iodine, together with intramuscular injections of the latter. Of his patients 68.8 per cent. survived, a proportion apparently higher than is ordinarily obtained.

3. Headache Associated with Intranasal Disorders.—L. Hemington Pegler classifies the nasal causative agents of headache into three groups, as follows: A simple or noninflammatory, a chronic inflammatory, and a group in which inflammation or congestion is present more or less actively. In the first group, headache is due to pressure somewhere within the nasal chambers of one more or less rigid body such as bone or cartilage against another, the richly innervated mucous membrane—often the cushion of the septum—intervening. This agent or force, while the most direct in operation, derives much importance through being often unapparent until a careful search by expert means has been made. A good instance is exemplified by a septal spine projecting against a middle or inferior turbinate far back and concealed by an anterior deflection of the triangular cartilage; such a condition may not be discoverable till after systematic packing of the nasal passages with gauze moistened in suprarenal extract and cocaine solution, or the adoption of some other mode of application of these agents, or even indeed until the anterior obstruction has been resected. The second or chronic inflammatory group includes intranasal changes that imply contact between less resisting surfaces, the morbid effects of any resulting pressure being presumably subsidiary to others of superior energy, some further explanation being desirable to account fully for headache. Simple degeneration of the turbinal or septal mucous membrane entailing softening of bone in more advanced middle turbinal disease, polypi, or polypoid degeneration, and possibly an allied condition affecting the walls or lining of one or more of the accessory sinuses, include the commoner types of pathological changes in this group. The third or inflammatory group embodies those cases in which headache is associated with rhinitis in its various forms, moist and dry, pain always tending to subside as congestion passes off. This group is typified in acute coryza, especially if it implicates the accessory cavities; sometimes also after nasal operations before reaction has subsided. Under obstructive conditions headache accompanies spasmodic rhinorrhea, either perennial or seasonal (hay fever).

1. The Treatment of Malignant Disease of the Skin. J. H. Sequeira.
2. A Report of the Work Carried Out at the Radium Institute, London, in 1914. A. E. Hayward Pinch.
3. Report on the Radium Treatment at the Royal Infirmary, Edinburgh, During the Year 1914. D. Turner.
4. The Phthisical Soldier at the Front. Sir Thomas Oliver.
5. The Treatment of Epidemic Cerebrospinal Meningitis. G. C. Low.

1. Treatment of Malignant Disease of the Skin.—J. H. Sequeira discusses the following measures at one's disposal for the treatment of malignant disease of the skin: excision, radiotherapy, radium-therapy, diathermy, and freezing by carbon-dioxide snow. Excision is the method of choice in squamous-celled cancer. With a view to preventing recurrence after excision it is well to give the patient a series of sittings under *x*-rays. In 1901 the author brought to the notice of the profession the treatment of rodent ulcer by *x*-rays. In order to overcome the difficulty in the treatment of the infiltrated edge of the rodent ulcer the author advocates preliminary curettage of the edge of the growth, followed by a series of *x*-ray exposures. If the case is going to do well by the *x*-ray treatment the improvement is shown at once. Small rodent ulcers, and especially those which are freely movable, react remarkably well

to radium. The use of diathermy requires further experience. In quite superficial cases of malignant disease of the skin good results have been obtained with carbon-dioxide snow. As regards the severe cases of cutaneous cancer great benefit may be derived from *x*-ray treatment, but care must be taken not to overdo this, for it is quite possible to stimulate an indolent process to one of greater activity by excessive *x*-ray treatment. In the treatment of Paget's disease the author advises an early removal of the breast and glands, should these be involved. In mycosis fungoides the *x*-rays act like a charm, but one cannot say that they are curative. In the multiple idiopathic sarcoma of Kaposi the author has seen the complete disappearance of the infiltration and growth under the *x*-rays.

5. **A New Treatment of Epidemic Meningitis.**—G. C. Low calls attention to the good results obtained by Shircore and Ross in the treatment of this disease by soamin in British East Africa. Epidemics of this disease are not uncommon in tropical Africa. Out of a total number of 143 cases observed by Shircore and Ross 127 were treated with the above drug. Excluding thirty-seven cases that died within sixty hours after admission to the hospital, which cases were regarded as malignant and beyond any known line of treatment, in the remaining ninety cases recovery occurred in 62.22 per cent. The serum treatment was found to be disappointing. Soamin is said to be a purer preparation than atoxyl. Intramuscular injections seem to act quite well.

Berliner klinische Wochenschrift

February 9, 1915.

Prophylaxis of Tetanus.—Ritter's article is in the nature of a proposition. He refers to Kreuter's statement that of every seven deaths among the wounded four have been due to tetanus. Otherwise stated 240 Bavarian soldiers have died from this malady since the war began. This number evidently includes only the milder wounded who could be sent home for treatment. The author personally has seen but one case at the western frontier, due to a grazing shot on the leg. The disease set in when the wound had nearly healed, and the patient was going about, and carried him off in two days, death having been due to spasm of the diaphragm. All the most successful remedies had been tested, save amputation, and authorities agree that this no longer has any status. Klapp believes that magnesium sulphate ought to save 80 per cent. of those attacked, but recent figures do not show fulfilment of this claim. The author saw three successive recoveries in tetanus of moderate severity at the eastern frontier as a result of repeated lumbar puncture. Serum he uses to ease his conscience, but, like others, he cannot see undoubted benefit. The recourse to magnesium sulphate seems to be a proof of its untrustworthy character, although an intensive technique seems to show at times that it can save life unaided. The question of prevention now seems to be of much greater importance than that of cure. The author, as well as Czerny, has seen clean-cut cases of death from tetanus after seasonable prophylactic injections, and hence does not feel like depending on it alone. The most important prophylactic treatment is the local management of the wound. In certain suitable cases the wounds should be excised, but it is doubtless an error to suture them. Bier's hyperemia treatment for the production of arterial stasis may be tested in threatening wounds, but we have no knowledge of the relationship of stasis to tetanus infection. Another point remains for consideration—the use of strong antiseptics, as the cautery, boiling oil, etc., as in former centuries. The author believes that balsam of Peru would do as well here as any other antiseptic.

Significance of Cholesterin for the Origin of Giant-Cell Tumors of the Tendons and Joints.—Weil refers at the outset to the relationship of these tumors to the sarcomata. At present the so-called sarcoma of the tendon sheath shows some analogies with granulomata. Each kind of tumor may contain giant cells. A third type of tumor has recently been invoked in this connection, viz., the so-called xanthoma cells, and a so-called sarcoma xanthoids has been described. This xanthoma cell is known to contain cholesterin, and is believed to have phagocytic properties. The author insists that xanthoma cells occur with a fair degree of constancy in the tumors of the tendon sheaths. This fact need not surprise for the same cells have been found exceptionally in various tumors and granulomata and even in old abscesses. The author now points out analogies between his giant cell tumors of tendon sheaths, xanthosarcomata and the ordinary xanthoma tuberosum multiples. In the ordinary manifestations of xanthoma of the skin (simple and tuberous) there is present a cholesterinemia. The author's task was therefore to discover if the normal cholesterin of the blood is increased in the tendon sheath tumors. He selected a case of xanthosarcoma of the ankle, which had been removed without recurrence; and found a large increase of cholesterin in the patient's blood. He concludes that whenever cholesterinemia develops some manifestation of xanthoma is likely to develop.

A Surgical Curiosity.—Under this title Sehrt describes the following case: A woman, aged 58, was kicked in the abdomen by a cow. The injury was followed at once by violent pains *in loco* and vomiting. This happened early in the forenoon. In the evening, the symptoms having persisted, operation was proposed and refused. The symptoms slowly increased in severity and on the next morning the vomitus was of the coffee-ground type. The author did not see the patient until 36 hours after injury. The abdomen was greatly swollen and sensitive to pressure. There was percussion dulness in the ileocecal region extending to the navel. No flatus was passing. Laparotomy was now performed by pararectal incision. Upon opening the peritoneal cavity, there spurted forth under high pressure pus tinged with bile and of an insipid odor. The serosa of the intestine was strongly injected and covered with purulent-fibrinous exudate. The right rectus muscle was then divided transversely, the whole intestine brought forward and examined. About 70 cm. above the valve, an intestinal tear was found. It measured 2 cm. and involved the mesentery. The mucosa at the tear was coerted. A marked hemorrhage into the mesentery caused great thickening of the latter. Abscesses had formed at the site of the tear, loops of the intestine constituting the walls. The first act was to suture the wound. The loops of intestine were then cleansed of fibrinous clots. No less than 8 collections of pus found between the coils were evacuated. One of these contained a very large specimen of ascaris lumbricoides. The abdominal cavity was now cleansed dry, the intestinal coils were replaced and the abdominal wound completely closed, but a loop of intestine well above the site of the lesion was sutured to the abdominal wall in case it should be necessary to reopen the wound. The lower angle of the latter was left open just enough to admit the pressure of a strip of gauze from the intestinal wound to the surface. On the next day the patient's condition had improved beyond expectation. However, during the ensuing day

vomiting returned and persisted three days. Then both feces and gas came easy and patient began to recover in earnest. On the 8th-12th postoperative days patient had fever which subsided when blood and pus were evacuated. The author believes that under the use of tamponade the patient would have died.

Injuries from Aviators' Darts.—Grützner calculates the force of impact of these projectiles. The latter must be launched at an altitude of 1,500-2,000 meters. Leaving out of account for the time the question of an initial velocity, by assuming that the darts are merely dropped overboard, mathematical calculations show that the force of impact of a dart upon the earth's surface would on an average be 3.128 kilogram-meters. An infantry bullet weighing 10 gms. dropped under the same conditions would have about one-half of this impact force. If, however, it was shot with a muzzle velocity of 885 m., the impact would be 8.55 kgm. The dart cannot penetrate bone, but has a way of traversing the soft parts in a peculiar fashion. It is able to pierce bloodvessels, penetrate several of the important viscera at once, and set up peritonitis. If the entrance wound is overlooked diagnosis may be very difficult. A case is given of an artillerist who while serving his gun chanced to look upwards for the presence of aeroplanes. At this instant he was struck in the left shoulder, and disabled. Borne at once to the field hospital a small entrance wound was found at the anterior border of the clavicle. An exit wound was found on the inner aspect of the left thigh. Death occurred from collapse within 24 hours. So much mischief was done by this dart that the autopsy report is a long one. There was extravasation of blood in the peritoneal and left pleural cavities; the mesentery was pierced in four places and the small intestine in twelve, and the dart had also passed through the stomach.

War Nutrition and Sick Diet.—Strauss states that one sees no evidence of famine in Germany. The lower classes, ordinarily the first to suffer, are, thanks to the paternalism of the Government, better fed than in peace times. This status, however, is somewhat offset by the ignorance or indifference of the socalled educated classes who pay no attention to the cessation of imports. The German physicians alone can bring the truth home to these people. A separate aspect of the problem is feeding the sick and the invalid. Those who have become more or less incapacitated by corpulence, as far as this is due to overnutrition, now have patriotic motives for correcting their habits, and should at once go upon an antifat regimen. The diabetic on the other hand has a large fat requirement, and fatty foods—butter, cream, oil, eggs, etc.—are expensive. He can get his fat, however, from fatty cheese, nuts, and olive oil. Protein he can obtain economically from smoked or dry salted meat or fish. When a meatless diet is to be carried out white cheese must be a standby. Legumes are now expensive, and the socalled "cutlets" made from them must be prepared instead from grits, etc. Milk, especially skim-milk, yeast, gelatin, may also be used as proteins or protein sparers. Sufferers from gastroenteric disturbances are usually forced to depend on eggs, butter, cream, fine starches, etc. Milk, butter, and eggs, even if sold at high prices, will be available, but cream may be prohibitive in price. To replace it white cheese and even rubbed up Swiss cheese may be used. Sugar is abundant. Wheat flour now contains 30 per cent. rye meal, and the finer grades of flour and starchy foods will perhaps not be available. Flour for baking (zwieback, rolls, etc.) will contain 50 per cent. of potato meal or other admixture. The Germans seem quite unaware of the possibilities of Indian meal, for Strauss mentions it only as a possible substitute for wheat flour. It is of course not well suited for the invalid. An ideal cheap dish for dyspeptics would appear to be potato flour cooked in skimmilk. Rice is getting short as well as cocoa and chocolate which means a hardship for the invalid. The healthy should deny themselves a little so that the invalid may have his proper nourishment. This may mean a more rapid return to complete health.

Treatment of Tetanus.—Wienert, in charge of a division of a reserve hospital gives at the request of his superiors his experience with tetanus from the outbreak of the war up to January 1. Forty-six cases of the disease have been treated in his wards. The first six cases were treated intensively in every way save that magnesium sulphate is not mentioned. All the cases were lost, whereupon additions in treatment were instituted. These included a hot bath of 25 minutes' duration every morning, and magnesium sulphate was used when convulsions were specially violent or otherwise menacing. This appears to have followed an earlier plan of injecting the solution at intervals or in a single initial dose. In the second series of 40 cases the author lost but 16, or in other words the mortality was 40 per cent. Even if we include the series of six consecutive deaths the death rate was but 48 per cent. It is difficult to assign the credit for this relatively good result. In the second series of 40 cases but one subcutaneous injection of serum was given (100 units). Morphine and especially chloral was given freely at night. Unusual pains were taken throughout with wound disinfection. In the first six (fatal) cases the author intimates that the amputations and resections made for prophylaxis may have aggravated the course of the disease, as also perhaps prolonged chloroform narcoses. In the second series he amputated only for cause and used no chloroform.

January 28, 1915.

Experiences with Furuncle Metastases.—Riedel concludes a serial article on this subject as follows: No furuncle, even the most insignificant, can be pronounced free from sequelæ. There are more deaths from furuncle metastases than from purulent thrombophlebitis. The young suffer more from bone metastases than do adults beyond the age of 25 years. Metastases in the soft parts of adults often cause disturbances which are more severe than the bone metastases of adolescents. Soft part metastases occur by preference in the brain, muscles, and especially in the perirenal tissue. At times the kidneys themselves are directly involved. The superficially seated boil can be treated at first conservatively by removing the most externally situated layers and then applying an ointment dressing. If the filtrate now rapidly appears a crucial incision should be made under ether spray, which must render the tissues bloodless or nearly so, deep seated furuncles should at once be incised, carbuncles at once extirpated.

Oxaluria.—Pincussohn believes that oxaluria represents a special anomaly of metabolism even if it sometimes complicates other conditions. Cantani has described the clinical expression of this metabolic disturbance as follows: loss of weight, muscular weakness and psychic depression. Rosenberg adds to this complex the frequent coexistence of intestinal disturbances. Nevertheless the disturbance of katabolism is not such as should damage the organism. The real menace is

calculus formation and this demands the correction of the metabolism. The treatment is two fold, dietetic and solvent. All vegetables which contain the preformed acid must be avoided. In addition any excessive acidity of the stomach should be corrected, and in fact attempts should be made to cause hypoacidity, which checks the absorption of oxalates. To keep the oxalates of the urine in solution one gives magnesia and phosphates. A mineral spring cure may be made to fill this indication. The only shortcoming of this general management is that it does not directly antagonize the endogenous formation of oxalic acid. We can cut off the external supply or diminish its absorption and we can render the combined oxalates soluble. But we have no causal therapy to oppose to the katabolic production of these bodies.

Pseudoappendicitis in a Physician.—Schatz describes a case of this condition which he studied on his own person. He was awakened with colicky pain unrelieved by a stool. Soon tympanites developed with pain and tenderness especially remarked in the appendix region, in which a circumscribed swelling could soon be felt. In a few hours, however, all these symptoms receded, so that in the afternoon the doctor arose and went about his business without further disturbance. Such phenomena were best explained by a temporary obstruction. He then recalled that he had eaten freely of mushrooms the day before. These perhaps had not been digested and had lodged *en masse* in the valves of Bauhini. Unfortunately, however, a study of the stools presented no evidence of any such happening. About two weeks later he went through a similar experience but on this occasion vomited. He called in colleagues who witnessed all the phenomena but had no belief in the existence of appendicitis nor of a stoppage from indigestible food. However, the next stool contained a piece of tendon, accidentally swallowed the evening before. The attack had passed off as before. The condition was somewhat obscure but there has been no recurrence since the author has eaten only digestible food and chewed it well. The author regards pseudoappendicitis or appendicolie as due at least at times to a "Bauhini spasm," which should yield to narcotics and antispasmodics. Adhesions doubtless favor such conditions although the author had never suffered from any inflammatory lesion in the bowels.

February 4, 1915.

German Ménus in War Time.—Schwalbe gives much interesting information and suggestions on food economies which are fairly well summed up in the bills of fare appended. For first and second breakfast he lays most stress on rye bread eaten with fruit jam or soft cheese. Meats can well be omitted at these meals. Sweetened decoctions of oatmeal or barley may be used as beverages and also to replace bread in part. The above is of course a necessity ménu, for the author allows as a rule a certain amount of wheat-and-rye bread, sausage, tea, coffee, and cocoa with milk and sugar, and a little butter. For the hearty midday meal he names a variety of soups, all of which contain potato along with legumes and scraps of meat. Wheat-flour porridge made with skim-milk is also recommended. Potatoes, cabbage, beets, turnips, green beans, etc., may be cooked together with a little fat meat. Sour krout may be cooked with pea-porridge, white beans with prunes, potatoes with dried apples or prunes; noodles eaten with fruit jam, and dumplings are good. All kinds of cereals may be cooked up in skim-milk and highly sweetened. A few of the cheaper fish, like herring, may be eaten. Meat economy is secured by days of abstinence, especially in warm weather. Fruit stews, tomatoes, etc., may be eaten as relishes. For supper rye bread and cheese forms the staple, with a little bacon or sausage after a meat-free dinner. Potatoes may be baked and eaten in the skins, with herring or bacon instead of butter. Generally speaking anything left over from dinner may be eaten for supper. Children must eat largely of cereals cooked in skim-milk. The author feels certain that while the combatants are fighting the enemy at the front the civil population will show equal patriotism and self-denial by fighting their appetites and overcoming their acquired habits of eating.

Hygiene in the Field.—Hesse calls attention to the difficulties of feeding troops at the front, especially in attempts to give them fresh meat, which is at times impossible, owing to local conditions. The use of canned meats is then advisable, and these, along with preserved vegetables, constitute the materials for a tasty meal. When there is beef to slaughter, examination of the meat cannot be vigorously conducted, and thorough cooking must be guaranteed These meats are eaten fresh; in other words, when tough, and make great demands on the teeth and digestive organs. However, the kitchen wagons, by cooking fresh meats at a very high temperature and under pressure, can overcome this drawback to some extent. These vehicles, through which it is possible to carry warm food to the front, are familiarly known as "goulash cannon." The field kitchens are provided with kettles which hold enough food for 200 persons each. In these vessels meat, potatoes, and vegetables are cooked together, while the bread ration is prepared in field bakeries. Feeding troops while on the march is naturally a different and most difficult problem. The bread, perhaps just from the oven, is packed tightly in wagons and readily becomes moldy in addition to being at times half baked. It can only be claimed thus far that the commissariat has been satisfactory. Some trouble during mobilization and rapid shifting of troops is unavoidable and hence expected. Fear of water shortage has been groundless, and although water must come largely from the supply of the conquered no evidence has been brought home that any intentional sophistication has been practised by the enemy. Dangers from water, so commonly expressed in bowel complaints, has been largely averted by drinking the abandoned native wines of the French. Cognac and other spirits have been taken only when well diluted, for fear of confusion with wood alcohol, which is somewhat used for beverage purposes (naturally with due precautions) in Belgium and France. Defecation is provided for in several ways—the regular privies of the conquered peoples (often shockingly primitive) serve for quartered troops; extemporized trenches, etc., are used in the bivouac, the contents covered with layers of earth, and, finally, the same recourse obtains in trench life, which is well adapted for defecation in extemporized latrines, dirt being always available to cover the dejecta. All these receptacles are provided with toilet paper, although as a rule any attempts at cleanliness in trench life are farcical.

Pleurisy Associated with Cholelithiasis. — G. Villa Santa believes that pleural complications of cholelithiasis are much more frequent than is generally realized. In the majority of cases of hepatic colic it is possible to detect pleural changes, chiefly on the right side, sometimes on the left side, and sometimes bilaterally. These changes consist as a rule of a dry pleurisy at the base of the lung. In violent, repeated, or protracted cases of cholelithiasis, complicated with angiocholitis, hepatitis or perihepatitis, there may result a scrofibrinous pleurisy. The cause of the pleural complications seems to be the transmission of inflammatory products by way of the lymphatics.—*Rivista Critica di Clinica Medica.*

Insurance Medicine.

The Relation of the Medical Profession to Accident Insurance.—In this age of high pressure living the protection of incomes against their possible loss or curtailment through illness or accident becomes a necessary part of the system. Dr. W. Edward Magruder, Baltimore, Md., states that the growth of short-term insurance in all of its forms has been the direct result of the needs of the times and its economic aspect cannot fail to be appreciated by anyone who gives the matter consideration.

Personal accident and health insurance, like that of insurance for life, has assumed two general forms —the industrial, which supplies the needs of the wage-earner who pays for it by the month or week, and the commercial or ordinary, which protects the business or professional man, who pays his premiums once, twice, or four times a year. This form of policy is based upon a contract or policy agreed upon by and existing between the company or insurer, on the one part, and the policyholder or insured, on the other. No medical examination is required as a condition precedent to the purchase of accident and health protection, but the statements made by the applicant in his application become part of the contract. The applicant furnishes to the insuring company an application, the statements in which he guarantees to be true, and agrees to pay the required premium provided the application is approved by the company, in return for which he receives a policy contract in which the company agrees to assume the liability as set forth in its several provisions.

The evolution of the accident and health insurance has been characterized by many circumstances which have influenced its development. Fortunately the time has come when the different companies have been forced to construct and sell extremely liberal policies, and the enactment of laws in the several states has thrown around these companies safeguards, which protect not only the public but the legitimately conducted insurance companies as well. The policies issued now are stated in simple language and their meaning is so well defined that litigation is seldom required as a means to their correct interpretation. The companies themselves realize that clean, honest business methods form the only foundation for their continued existence.

This continued improvement in administration has gradually caused an increased demand for the services of the medical profession, in the following ways: 1. Physicians may be medical examiners for accident companies. 2. They may be attending physicians to persons who are insured in accident companies. 3. They may be interested in the valuable statistics which accident companies will ultimately contribute to the field of preventive medicine. 4. Physicians may themselves be policyholders in accident companies.

The frequency with which companies will call upon examiners in future to make medical investigations and report truthfully upon the facts and circumstances relating to the disabilities of policyholders will be greatly increased. Companies are compelled not only to pay their just claims, but to be able to show in the shape of papers in their claim files, that they are fully justified in any final action they may have taken. It will be upon the reports of their medical examiners that definite decisions will be made. The importance to these companies of physicians who are capable examiners and able to correctly estimate the duration of the disability and to report it with equal fairness to the company and the claimant can scarcely be estimated.

As attending physicians of patients insured under accident and health policies, the members of the medical profession are in almost daily contact with the accident insurance business. Each policyholder is compelled to furnish one or more statements from his family physician upon blanks furnished by the insurance company, and when indemnity is demanded, the final action of the company is taken and payment made upon the facts furnished by the attending physician as well as those from the company's agent, the claimant, etc. In these cases, sometimes the role of the attending physician is not a pleasant one. He is in a position where he may have to decide whether he will answer the questions fully and frankly and perhaps incur the displeasure of his patient, who may be endeavoring to press an unjust claim, or give evasive answers and allow the company to guess at the entirely true facts, and perhaps to make a wrong guess.

The influence which can be exerted by the medical profession in educating the public to deal squarely with corporations and to be satisfied with just treatment at their hands is greater than is realized. This, coupled with the reporting of any irregular transaction, of wildcat schemes, and dishonest methods and agents when known, to the proper authorities, will do more than anything else in placing the accident insurance business in a position where justice may be done to all.

From the standpoint of preventive medicine the business of accident and health insurance is going to prove of great interest. Statistics relating to the recurrent diseases, and diseases and injuries in their relation to occupation, locality, and special conditions are being collected by these companies, and will determine with greater accuracy than has been possible previously many facts of interest to the whole field of medicine.—*Southern Medical Journal,* August, 1914.

Probable Cause for Prosecution of Examining Physician.—In 1910, a number of insurance companies doing business in Louisville, Ky., learned that they were being defrauded as the result of a conspiracy of their agents to procure insurance upon the lives of unfit persons by false applications and answers, and by the substitution of healthy persons for examination in lieu of the unfit persons named in the applications. They instituted an inquiry, in the course of which it was found that an insurance company's examining physician had apparently reported favorably on applications for insurance from persons who were not fit subjects for insurance.

The physician was summoned to appear before the grand jury, which returned an indictment against him. He was subsequently acquitted, and brought a suit against the insurance company for damages, charging that the prosecution against him was instituted by it maliciously and without probable cause. It was held that, in the circumstances, there was probable cause for a criminal prosecution against him, though it subsequently appeared that he was imposed upon by the substitution of different persons instead of those who were applying for the insurance.—Schott v. Indina Nat. Life Ins. Co., Kentucky Court of Appeals, 169 S. W., 1023.

Book Reviews.

Œdema and Nephritis. A Critical, Experimental and Clinical Study of the Physiology and Pathology of Water Absorption in the Living Organism. By Martin H. Fischer, Doctor of Medicine. Eichberg Professor of Physiology in the University of Cincinnati; second and enlarged edition. New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Limited, 1915.

The first edition of this work was published in the form of two monographs, one of which dealt with edema and the other with nephritis. That on edema was the Nathan Lewis Hatfield prize essay of the College of Physicians of Philadelphia for 1909, and that on nephritis the Cartwright prize essay of the Alumni of the College of Physicians and Surgeons of Columbia University, for 1911.

The attempt is made to prove experimentally and clinically that the cause of edema resides in the tissues, which become edematous, not because water is forced into them, but because they suffer changes which induce them to suck up water. Dr. Fischer is of the opinion that this is proved by the fact that the severest grades of edema may be produced in the entire absence of local circulation, and consequently in the entire absence of any blood pressure. More specifically, edema proceeds from any condition which leads to the production of acid in the tissues. According to Fischer any colloid placed in an acid medium will swell on account of water absorption. The amount or degree of edema, will depend upon the nature of the acid, as well as the degree of concentration. The rôle of other agencies besides an increased acid content in the development of edema is discussed, but the whole gist of the argument lies in the assertion that the cause of edema resides in the tissues and that acid in the tissues is the chief causative factor.

The studies in nephritis are a continuation of the experimental studies in clinical physiology made in edema. Fischer's thesis with regard to that combination of conditions known as nephritis, is that the changes which characterize the disease are colloid chemical in nature and due to a common cause, the abnormal production or accumulation of acid and of substances which in their action upon colloids behave like acid in the cells of the kidney. To the action of these upon the colloid structures that make up the kidney are due the albuminuria, the specific morphological changes noted in the kidneys, the associated production of casts, the quantitative variations in the amount of urine secreted, the quantitative variations in the amount of dissolved substances secreted, as well as the other signs of nephritis which appear in direct connection with the kidney. As a matter of fact, the argument regarding the nature and cause of nephritis is much the same as that given by the author for the nature and cause of edema. From his point of view, nephritis is, to a large extent, an edema of the kidney.

As for treatment, after the avoidance and removal as far as possible of every condition that favors the abnormal production or accumulation of acid in the kidney, Fischer says that "the rule to be followed may be summarized in the words: Give alkali salts and water and give dextrose."

Glaucoma, in accordance with these views, from a pathological standpoint represents one of the local edemas, and from a clinical standpoint all its signs and symptoms are referable to the increased intraocular pressure resulting from the edema. Thus the problem of glaucoma and its treatment is identical with that of nephritis.

The theory of the author that the colloids of the tissues and their state are primarily responsible for the amount of water held by them runs counter to all the theories of water absorption held at the present time. But in accounting for the causes of edema and nephritis Fischer has experimentally and clinically put forward a strong case. He has marshalled the facts ably, and his whole argument, if not without flaws, is at any rate, worthy of sérious consideration.

Public Health Laboratory Work. By Henry R. Kenwood, M.B., F.R.S. Edin., Chadwick Professor of Hygiene and Public Health, University of London, etc. Sixth Edition. Price, $4 net. New York: Paul B. Hoeber, 1914.

This volume is devoted to the chemical examination of water, air sewage, and food and a chapter on the examination of disinfectants. In this edition practically all reference to bacteriological examination has been omitted in order not to enlarge the work unduly. Clearness is obtained by describing but one method for each purpose, the author selecting, in each instance, the one dictated by experience as being the best. Public health chemists will need no introduction to this work, which has become a standard, and it need only be said that this edition has been kept well up to the grade of the former ones.

Modern Medicine. Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by Sir William Osler, Bart.; M.D., F.R.S.; Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in Johns Hopkins University, Baltimore; formerly Professor of Clinical Medicine in University of Pennsylvania, Philadelphia, and of the Institute of Medicine in McGill University, Montreal, Canada; and Thomas McCrae, M.D., Professor of Medicine in the Jefferson Medical College, Philadelphia; Fellow of Royal College of Physicians, London; formerly Associate Professor of Medicine the Johns Hopkins University. Volume IV—Diseases of the Circulatory System—Diseases of the Blood—Diseases of the Lymphatic System—Diseases of the Ductless Glands—Vasomotor and Trophic Disorders; second edition; thoroughly revised. Illustrated. Price, $5.00. Philadelphia and New York: Lea and Febiger, 1915.

This fourth volume maintains the high standard set by the previous volumes. The material contained in the first edition has been carefully revised and the most recent views expressed by American and British authorities of medicine are incorporated in the present volume.

The diseases of the pericardium are ably and exhaustively dealt with by Dr. Alexander McPhedran. Perhaps, the most instructive article in the volume is that by Dr. Thomas Lewis on the rate and mechanism of the heart beat. Dr. Lewis is one of the foremost exponents of the teaching of what may be termed the new school of the theory and practice of heart affections of which James Mackenzie is the pioneer and great apostle. Lewis himself is an originator of mechanical methods of testing and recording the action of the heart, and discusses the subject in a masterly manner. He points out in the course of his remarks that the irritable heart of soldiers is a sequence of any long-drawn-out military campaign. This form of heart disorder is characterized by a persistent tachycardia, and is a symptom often witnesed in young and raw recruits who have been subjected to long and arduous work on the battlefield or in the trenches.

Dr. Robt. H. Babcock discusses the diseases of the myocardium. Sir William Osler hypertrophy of the heart. Dr. Alexander G. Gibson contributes a remarkably clearly written article on insufficiency and dilatation of the heart. Referring to the effect of blood pressure on heart failure, the writer says that the hope that some indication of the state of the heart was to be found in the records of blood pressure has hardly been justified. The diseases of the valves of the heart are discussed by Sir William Osler and Dr. Gibson. The article on functional diseases of the heart is contributed by Dr. Charles F. Hoover.

The longest and certainly one of the best articles in the book, dealing with congenital cardiac diseases, is written by Dr. Maude E. Abbott in which she concludes that the cause of the defect is clearly to be sought in the immediate environment of the developing embryo.

Osler discusses diseases of the arteries and in commenting upon the causes of arteriosclerosis, he is not inclined to attribute to alcohol in itself the predominant rôle in the causation of the condition which is ascribed to it by some authorities. He cordially agrees with Abbott that "one main cause of rising arterial pressure in middle life is excess of feeding, that is to say, of food in excess of work and excretion." As to the causation of aneurysm Osler states that high blood pressure next to destruction of the elastic fibers of the media by a mesaortitis is the most important single factor.

The diseases of the ductless glands are fully considered. The diseases of the adrenal glands, the pituitary body, acromegaly, hypopituitarism, polyglandular syndrome, the pineal body and diseases of the thyroid gland are made the subject of a series of exceptionally excellent articles by Dr. George Dock. Dr. Warthin writes concerning athyreosis, athyroidism, hypothyroidism, cretinism, myxedema, the parathyroid glands and diseases of the thymus.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held January 19, 1915.

DR. T. STUART HART IN THE CHAIR.

Osteitis Fibrosa.—Dr. JESSE G. M. BULLOWA presented this patient and showed lantern slides illustrating the condition found. The interest of this case lay in the rarity of the reports of similar cases, and in the opportunity it offered to study the relationship of this condition to those closely associated, namely, osteitis deformans, osteomalacia, and ordinary rickets. In his posthumous work on "Rickets and Osteomalacia," Friedrich von Recklinghausen, who first described the condition in 1891, classified it as a metaplastic malacia in which fibrous tissue replaced bone marrow in a manner analogous to the parenchyma replacement in such diseases as cirrhosis of the liver or myocarditis. Of the one hundred or more cases which had been reported comparatively few had any hematological or roentgenological data, or were reported from other than the surgical standpoint. The patient, a man 42 years of age, a native of Sicily who had been in this country for ten years, came under Dr. Bullowa's observation eight months ago. At that time he complained of severe pains in the shins which had lasted for seven or eight months; he had been bedridden for three and one-half months. There were flattened ovoid swellings, symmetrically placed on both tibiæ, that on the left being receding. The swelling fluctuated and had hard crater-like margins. There was tenderness but no egg-shell crackling. The swelling on the right tibia was incised in February, 1914; only grumous material was obtained. The lesion was regarded as luetic and salvarsan was given. The patient had complained of severe general joint pains, especially in the sacral region, for twelve years. Four years ago his left femur was fractured by a fall from a horse. He had also complained for five months of pains in the lower ends of the thighs and upper ends of the legs, which was worse toward evening and on damp days. An *x*-ray examination made by Dr. Gottlieb revealed the nature of the condition. The patient's skin was dark, his mucous membranes pale. There was pigmentation over the cysts which appeared on the surface of the tibiæ. The hair on the scalp was abundant and soft; on the face it was scant, neither was it abundant in the axillæ or the pubes. There was marked pyorrhea. The tonsils were enlarged and some of the crypts were filled with detritus. The heart and lungs were negative. The liver was palpable one finger below the free border of the ribs when the patient came under observation; at present it could not be felt. The spleen was not enlarged. There were enlarged axillary nodes in the left axilla, but no enlargement of the epitrochlears. Examination of the osseous system showed enlarged tender bones which were markedly bowed. There was evidence of an old fracture of the lower end of the right femur and also a bony outgrowth at the lesser trochanter. The nervous system showed no change. During his stay of several weeks at Mount Sinai Hospital the patient's temperature rose in the evenings to 100.5° F. Aside from a period of several weeks in July when the pain in the knee joint and tibiæ was very much worse and the crater on the right tibia was surrounded by edematous swelling, the patient had improved steadily. The episode of pain and tenderness yielded to aspirin and methyl salicylate locally applied. The general therapeusis consisted of phosphorus 1/20 of a grain in cod liver oil, and calcium lactate. For several months the patient received pituitrin hypodermically and later citrate of iron and ammonia hypodermically. The blood gave a positive hemolytic streptococcus; hemoglobin was 77 per cent.; red blood corpuscles 4,520,000; white blood corpuscles 8,500. The differential count showed small lymphocytes, 28 per cent.; large lymphocytes, 8¼ per cent.; neutrophiles, ¾; basophiles, ¾; neurophiles, 61 per cent.; basophiles, ¼, and eosinophiles, 1 per cent. The urine when the patient came under observation showed a trace of albumin, but recently was negative aside from a low specific gravity. There was a localized thickening of the right eighth rib; there were no changes at the costa-chondrial junction. The tibiæ showed marked bowing and enlargement of the Haversian canals with cavity formation in various stages. Dr. Gottlieb's report of the *x*-ray findings showed the fifth metacarpal of the right hand bowed but there was no evidence of Haversian canal dilatation. There was a similar bowing of the fifth metacarpal of the left hand. The feet showed no changes. Examination of the skull showed the sella turcica normal, increased density of bone, and a small focus of absorption in the vault near the vertex. The head of the ulna showed dilatation of the Haversian canals more marked on the right side than on the left. The lower end of the humerus showed very early changes with beginning cyst formation. It was important to differentiate this disease from conditions due to syphilis, tuberculosis, and malignant disease with cyst formation. It was quite evident from its symmetrical and widespread distribution that it was a systemic disease characterized by dilatation of the Haversian canals with cyst formation. The involvement was usually in the diaphysis; the epiphyses escaped. This was the only case which the author could find in a search of the literature in which a rib had been involved. Histologically the cases studied showed a rarifying osteitis with fibrous tissue replacement. The close relationship of this disease to Paget's or osteitis deformans, osteomalacia, and rickets was evidenced by the osteoporosis and the hyperostotic process which in this case were both well marked. This case showed the typical Recklinghausen cyst formation side by side with the thickened skull and bowed tibiæ of Paget's syndrome.

Dr. ARTHUR BOOKMAN called attention to the important pathological relationship of osteitis fibrosa and conditions like osteomalacia. Von Recklinghausen had indeed described the early stage of osteitis fibrosa as an osteomalacia. Osteogenesis imperfecta, idiopathic osteopsathyrosis, osteomalacia and perhaps rickets all seemed to have in common certain pathological factors. In all of these conditions there was evidence—as yet not altogether conclusive—that the disturbance in bone formation was due to alterations in the functions of the organs of internal secretion. His own work and that of others had shown that in all the conditions mentioned at some time during the course of the disease there was a loss of calcium by the body. It was of interest that three cases of osteitis fibrosa had recently been described showing changes in the epithelial bodies. In another case administration of calcium lactate had been followed by an increased calcium retention and by clinical improvement. It would be of interest to try the effect of calcium therapy on Dr. Bullowa's patient.

Dr. HENRY CLARKE THACHER said that the end of the tibia appeared to be denser than was usual. The areas of absorption were clear cut and not punched out as in tumors. There was not the gradual transition such as was seen in osteitis deformans.

Dr. BULLOWA said that the patient had had the milk in his dietary increased and had received calcium lactate. There were about 106 cases belonging to this group on record. None of the cases reported had shown Bence-Jones albumose.

Report of a Case of Typhoid Fever Complicated by a Pure Typhoid Pneumonia and Pulmonary Abscess.—Dr. SEYMOUR BASCH presented this report. He stated that the etiological factor in these pneumonias was a very interesting point. It was admitted that a true pneumococcus pneumonia did occur in typhoid fever; still, in a number of cases, as in the one herewith reported, careful bacteriological search, sometimes even at autopsy, failed to demonstrate the presence of any other than the Eberth bacillus. It would, therefore, be logical to conclude that these were true typhoid bacilli pneumonias. This conclusion was the more readily acceptable when one recalled that Jehle, in 1902, demonstrated the presence of typhoid bacilli not only in the sputa, but also in the pulmonary secretions of pneumonias complicating typhoid fever. He even succeeded in demonstrating the bacilli in the sputa of clinically and anatomically uncomplicated bronchitides. Osler had pointed out that in the pneumonias of typhoid fever the pneumococci might have originally been present and the typhoid bacilli might be only secondary invaders. From statistics it seemed that pneumonia in typhoid fever was by no means as frequent as had been supposed; Frankel found it in 1.2 per cent. of 500 cases; Norris 1.2 per cent. of 4,459 cases, and Osler in 1.5 per cent. of 1,500 cases of typhoid fever. The case reported was that of a man, 38 years of age, whose personal history was negative. His present illness began eleven days before admission to the Lebanon Hospital, Nov. 25, 1914, when he felt chilly, feverish, and had a sore

throat for two or three days, but was able to continue at his work. Nine days before admission, he began to have headache, diarrhea, and great weakness, persisting until the time of his admission to the hospital. At that time he was having as many as twenty loose, greenish-yellow stools daily. He had daily chills lasting five or ten minutes. At the onset of his illness his temperature was 104° F. but dropped to 101° the day before his admission. There was no nausea, vomiting, cough, or hemorrhage. At the time of admission his temperature was 105° F.; pulse 102, and respirations 30. There were no focal signs of disease anywhere; the chest examination was entirely negative. The spleen was distinctly enlarged. The blood examination showed 13,000 leucocytes of which 84 per cent. were polymorphonuclears and the remainder mononuclears and lymphocytes. The leucocytes increased the following day to 18,000 and after that fluctuated between 10,000 and 18,000. The erythrocytes averaged about 4,000,000. The initial blood culture proved sterile, but repeated positive after one week. The early stool cultures showed *B. coli*. Except for a temporary trace of albumin and casts after one month, the urine showed no renal involvement. The temperature, after an initial rise to 106.4° F., fluctuated between 103.5° and 105° until the fourth day when it dropped to 100°, and thereafter remained between 102° and 105° for nine days when there was a critical drop to from 104.5° to 97.50° F. The fourth day the patient began to complain of pain on the right side of the chest, and following this he developed the symptoms of acute lobar pneumonia. Cultures of the sputum failed, however, to show any pneumococci, but repeatedly even as late as Dec. 27, over two months after the onset of his illness, showed pure cultures of the typhoid bacillus. Examinations for the tubercle bacilli were negative. On the third and fourth days of his pneumonia there was bronchial singultus which finally apparently yielded to atropine. On each of these two days the patient had a chill lasting fifteen minutes; he had a similar chill on the sixth, tenth, and thirteenth days of the pneumonia. Each rigor was succeeded by a moderate rise in temperature. Following the subnormal drop in the temperature on the ninth day there was a chill and a rise to 105° F. The temperature thereafter rose and fell sharply between 100° and 105° for about a week, since which time it had been fluctuating irregularly but had shown a decided tendency to become lower. The pneumonia symptoms began to clear up while new subjective symptoms began to appear in the anterior portion of the lobe, including numerous coarse bubbling râles, amphoric breathing, dulness, etc. An *x*-ray at this time showed an abscess of the lung at the angle of the scapula and near the base of the lung. An *x*-ray taken a little later showed evidence of clearing up of the focus in the lung. On account of the poor condition of the patient and the tendency of the abscess to improve as shown by the *x*-ray operation was deferred. The patient about a week later complained of localized tenderness and pain in the upper right quadrant of the abdomen, beneath the ribs. Exploratory punctures in this area as well as posteriorly failed to show any pus. Meanwhile, under expectant treatment, the condition of the patient improved. Very recently he had developed physical signs that indicated the presence of a suppurative process in the posterior part of the lungs, but despite this his general condition indicated that he was on the road to recovery.

Dr. T. STUART HART asked Dr. Basch if he had regarded the process in the lung as a local effect of Eberth's bacillus. Dr. Hart had recently had under observation a case of typhoid fever running a very severe course terminating with a lobar pneumonia; the interesting feature in this case was that blood cultures revealed both Eberth's bacillus and the pneumococcus. Might not Dr. Basch's case have been infected with more than one organism?

Dr. BASCH, in answer to Dr. Hart's query, said that he tried to bring out the fact that there were only present pure typhoid bacilli and no pneumococci at all. The sputum was carefully examined and they were never able to find any pneumococci. The typhoid bacilli were found in the blood and in the sputum in pure culture. An interesting point in this case was that ten or eleven days before the patient had had a sore throat, malaise, and headache, the symptoms of tonsillitis. It was rather problematic if this was not an early case of "tonsillo-typhoid," such as had been described by Strümpel and other Germans.

Diagnosis, Symptomatology, and Therapy of Dilatation of the Descending Thoracic Aorta.—Dr. SELIAN NEUHOF read this paper, the object of which was to indicate through illustrative cases the comparative frequency, diagnosis, symptomatology, and therapy of aneurysmal dilatations of the descending thoracic aorta and to present its claim to a clinical entity. Recent reports of aortitis were almost entirely confined to disease of the ascending or transverse aorta with fragmentary or no reference to the descending aorta. The author reported six cases in five of which the Wassermann test was done. It was positive in two of these, negative in three. Three of the cases had slight symptoms when treatment was begun; these were clinically cured. Of the cases with severe heart failure, the one with luetic lesions alone was very much benefited; another who had apparently had a luetic infection engrafted upon an old endocardial lesion was only moderately improved. In three cases the correct diagnosis was made regarding the descending aorta by the presence of an impacted area to the left of the sternum at its middle third, and by the localization of abnormal aortal sounds most prominently over this area. Sharp, continuous, gnawing pains, such as those often associated with sacculated aneurysms were not prominent features of the dilated descending aorta. Substernal pains or those referred to different parts of the chest, neck, jaws, or head were most apt to incur upon exercise. Another group of symptoms was that due to cardiac decompensation. This was not necessarily a marked clinical feature; in fact, in three of the cases reported it consisted only of a slight dyspnea upon exertion. Edema was usually slight and confined to the legs; it was extreme in neglected cases or very late in the disease. Dyspnea was of the usual cardiac type, generally most marked on exertion, though it might be continuous in severe cases of cardiac failure. Left ventricular hypertrophy of various degrees was usually present. The heart was occasionally tremendously hypertrophied before cardiac failure set in; this in itself was highly suggestive of cardiac lues. In dilatation of the descending aorta the abnormal sounds in typical instances were best heard at the left sternal border at its middle third or from the third left intercostal space to the ensiform. This latter area of propagation was somewhat similar to that occasionally found in valvular aortic regurgitation. The sounds over the impact area were the rough first and accentuated or liquid second sound which usually served as differential guides. There was usually a rough systolic murmur over the dilated aortal area; the second sound had a liquid rather than an accentuated tone, and was usually prolonged so as to occupy the entire diastole or was followed by a diastolic murmur of varying intensity. By placing the eye on a level with the patient's chest, a distinct heaving area distinguishable from that at the apex and occupying the lower left sternal intercostal spaces could often be noticed. A sensation of impact was also given to the bell of the stethoscope when, during the usual clinical examination, it was placed over this area. All these signs were made more evident by having the patient hold his breath at the end of expiration. Occasionally difference in the time of thrust between the apical and left intercostal areas might be noticeable by placing one finger over the apex and the other over the left sternal border; since, however, this difference physiologically was 0.07 second, it might be impossible to distinguish it by palpation. Another method was by the use of a differential stethoscope, that was, an ordinary pair of ear tubes arranged with two bells, one over the apex and the other over the dilated aorta. When the murmurs were not too loud, the difference in the time impact might thus be determined. It was important to distinguish the aortic impacts to the left of the sternum from those found in patients with marked left ventricular hypertrophy or in healthy individuals with overacting hearts and thin chest walls, but the auscultatory signs above described were then absent. In four cases electrocardiograms were taken; three showed complexes of left ventricular preponderance, the fourth was normal. To clinch the diagnosis *x*-ray examinations by means of the fluoroscope or roentgenograms were absolutely essential. The physical signs of all the cases were most prominent to the left of the sternum at its middle third, when clinical symptoms were present; the signs became less with the patient's improvement. The disease might run a mild course lasting many years. Intensive anti-luetic treatment—salvarsan, mercury, and iodide of potassium—was indicated in every case.

Dr. WILLIAM C. LUSK said that he had done a num-

ber of autopsies on cases of thoracic aneurysm, and from his observations of autopsy findings and of clinical manifestations he thought the shortness of breath in these cases was due to the narrowing of the respiratory passage from pressure of the aneurysm on the trachea and left bronchus. A thus narrowed trachea accumulated mucus at or below the seat of stenosis which temporarily compromised the respiratory excursion and thereby increased the dyspnea, so that often in the early morning the patient was awakened by the shortness of breath from which he got relief by coughing up the mucous accumulation. His work on the medical treatment of thoracic aneurysm had developed as a result of his original interest in the Moore-Corradi operation of wiring with electrolysis. While in certain cases, particularly where pain was a prominent symptom, the wiring operation would give prompt relief, the ultimate result after wiring, before the beneficent effects on aneurysm of salvarsan in proper combination with the older antispecific remedies had been learned, was always unsatisfactory because of the recurrence of the symptoms in from one to several months. Thus the problem had early presented itself as to how to prolong the lives of these unfortunate cases. In connection with the use of modern antiluetic therapy for aneurysm, he had reached the conclusion that a more or less definite procedure in the administration of the remedies must be followed to attain good results. One patient, wired in March, 1912, who is today living in comparative comfort and enjoying moderate activity, one month after the operation developed attacks of strangulation during which he could hardly get air either in or out of his lungs and his whole body would become a livid blue color. These attacks could be temporarily relieved by a hypodermic of morphine. Finally right after receiving an injection of 1 grain of mercury salicylate, which had been given intramuscularly on the advice of Dr. John A. Fordyce for its quicker effect, together with potassium iodide, the patient experienced a diminution in the severity of the attacks and in a day or two the latter ceased for the time being. Four months later, the patient, having in the meantime taken mixed treatment, following severe exertion had a recurrence of the attacks of strangulation which again ceased soon after one injection of mercury. But the patient now suffered from much pain and shortness of breath. The condition was desperate and then it was that in spite of all the warnings not to give salvarsan in arterial disease, there being in this case nothing else which could possibly hold out any hope, after consultation with Dr. E. L. Keyes, Jr., neosalvarsan was administered intravenously, following which the symptoms promptly ameliorated. Next, Dr. Alexander Lambert gave neosalvarsan to a patient with thoracic aneurysm at Bellevue Hospital, who was suffering such great pain that he was unable to lie down on that account, and relief soon followed. These experiences seemed to speak so strongly for the value of salvarsan in aneurysm, that the importance of the other antispecific remedies was temporarily lost sight of. But after a time it was concluded that salvarsan given in successive doses independently of the other antispecific drugs, was decidedly injurious to these patients. The speaker's attention was first called to this fact through a patient whom Dr. George A. Tuttle had kindly asked him to treat at the Presbyterian Hospital. Two casts of this aneurysm which projected from the front of the chest wall, taken eleven days apart, showed a perceptible increase in size while salvarsan treatment was in course of administration. Three other aneurysms then on salvarsan alone, were also doing badly. With the stopping of salvarsan and the giving of mercury they all got better. Two of them, however, who had had small doses of salvarsan as their chief treatment at intervals over a period of several months and whose symptoms had ultimately become worse, soon died, one from rupture of the aneurysm and one from a bronchorrhea accompanying great pressure on the trachea. Following this it was concluded that mercury should support the salvarsan.

The importance of potassium iodide was impressed very forcibly by a case which was referred by Dr. Van Wagenen, who had shown the case at a previous meeting of the Academy of Medicine, as one of vocal cord paralysis due to aneurysm of the aortic arch. At the time when this case first came under Dr. Lusk's observation he could discover in him no physical signs of thoracic aneurysm. There was no vocal cord paralysis any longer and the comparison of an *x*-ray picture with one taken 16 months previously, both in the same position and at the same focus, showed that the aneurysmal shadow had diminished from 1 to 1¼ inches in its transverse diameter. The contrast was so great that Dr. Van Wagenen was called upon to come down and identify the patient, which he did. The treatment which the patient had had for the 16 months was then carefully investigated and it was found that for 23 weeks of this time potassium iodide had been taken in 5 and 10 grain doses, besides which 9 injections of salicylate of mercury, ½ grain each, had been given. This same patient had also at previous times had considerable potassium iodide in small doses. Finally it was observed, and the observation is believed to be one of the greatest importance, that those patients who derived the most benefit from the salvarsan were the ones who had previously been taking the mixed treatment. Lesser of Berlin states that in treating tertiary syphilis potassium iodide and mercury should always precede the administration of salvarsan.

Dr. Lusk said he believed that a long treatment with potassium iodide, 10 grains, t.i.d. for 4 or 5 months, and during this time the administration of about 15 intramuscular injections of mercury salicylate not over 1 grain each, or less if the patient could not take so much, should be given before administering salvarsan. He believed that the prior control of the gummatous infiltration in the aortic wall by the older remedies gave some added advantage to the germicidal action of the salvarsan in contributing benefit to the patient. Before giving salvarsan he always stopped the potassium iodide, since in his observation potassium iodide in combination with or following salvarsan had, in some cases of aneurysm, caused pain or increased expectoration and cough. With the stopping of the potassium iodide in such cases, these symptoms would ameliorate or disappear. Injections of mercury he believed were important to support the salvarsan, but whether they should be given in combination with a course of salvarsan, taking care not to give the two drugs too near together, or following a course of salvarsan, he was not sure. He was inclined to believe, however, that the combined use of these drugs was productive of the best results. Some German observers did not give mercury in combination with salvarsan on account of the danger of nephritis. He believed that if mercury were given in combination with salvarsan at least a five-day interval should be left between doses, and that two injections of mercury should be given for every one of salvarsan. The urine should be carefully watched. He preferred neosalvarsan to salvarsan because Alwens had demonstrated experimentally that neosalvarsan given in proportionately large doses to rabbits was little liable to produce nephritis while old salvarsan in lesser dosage was very liable to do so. Alwens had quoted Wahle as having twice seen a very severe hemorrhagic nephritis following the intravenous injection of neosalvarsan 0.9 gm. He himself gave neosalvarsan in doses of 0.45 gm. in 100 c.c. of freshly distilled water at intervals of 15 days.

Dr. George Reese Satterlee said that the great difficulty lay in following these cases long enough, on account of the nature of the trouble. It was, therefore, often very difficult to give the results of treatment. The patient he showed before this section in 1911 was a very interesting case having a large double aortic aneurysm with a much distended aorta similar to Dr. Neuhof's case. In this instance he started treatment with a few doses of salicylate of mercury and when the man was in very serious shape. He had marked dyspnea, pain, and paralysis of his left vocal cord, with absence of left radial pulsation. The *x*-ray showed the outlines of the aneurysm. After a few days' treatment with salicylate of mercury there was little if any improvement. He then gave doses of four-tenths of a gram of salvarsan and with remarkable results; in two and a half days he came in very much improved, the dyspnea especially so, and the pulse had returned on the left side. The paralysis of the vocal cord began to clear up and eventually cleared up entirely. He was given two more doses of salvarsan and since then no more salvarsan. He was given salicylate of mercury at regular intervals. He had received since 1911 from 115 to 120 injections, of one grain each; also 90 grains of iodide of potassium per day, up to tolerance. Whether this was necessary or not was a vague point. The pain was intercostal in character and was due probably to the pressure of the aneurysm itself. The periaortitis had a great deal to do with the symptoms. Subsequent radiograms showed no change apparently in the aneurysm but did show a change in the peri-

aortitis. There was ¼ reduction in size, as shown in subsequent radiographs and an evident relief of the pressure on the recurrent laryngeal nerve. Dr. Satterlee thought that the dyspnea in this as well as other similar cases that he had seen was probably due more to a myocarditis than to any actual pressure upon the aneurysm itself, although in some cases, symptoms are due to direct pressures. The patient would probably not become a perfectly well man but he now was able to attend to his duties as chef. The pain had entirely disappeared but the aneurysm was still present.

Dr. Seymour Basch said that the patient who had been reported from his service had been admitted to the hospital with a diagnosis of carcinoma of the esophagus. He had trouble in swallowing which was progressive and finally he was scarcely able to swallow even liquids. The clinical examination gave no evidences of an aneurysmal dilation or aneurysm at all. There was no change in the radial pulsations; there was no murmur and no involvement of the recurrent laryngeal nerve. The diagnosis of aneurysmal dilatation was made by the *x*-ray. In view of the fact that the patient had had an old cardiac condition he refrained from using the bougie, deciding to submit the patient to the *x*-ray first. This was a point of very great importance because the bougie might have done much harm, even to causing perforation of the sac and death. Another very important fact in the history of this patient was that he gave a history of having had syphilis. They were more and more being brought face to face with the fact that cardiac disease arose far more frequently on the basis of syphilis than had been formerly supposed. To recapitulate, he said, that one should not be in a hurry to make a diagnosis of carcinoma simply because the patient happened to be a middle aged man, who had esophageal obstruction and that one should not be in a hurry to bougie in suspected cases of esophageal stricture. He advised that one should first proceed with the milder methods in making his diagnosis and reserving the harsher ones, if these were necessary at all, for later use when he knew it would be safe to employ them.

Dr. S. Neuhof did not think that cases of this sort were amenable to treatment by wiring. They were too deep seated and it was a difficult and dangerous procedure to attempt to introduce wires. Dr. Satterlee had brought out a point which he emphasized in his paper, namely, that many of these patients with aneurysm, sacculated or fusiform, showed a marked improvement under treatment and without any alteration in the size of the aorta. The condition seemed to be controlled by the treatment.

Demonstration of Roethlisberger's Clinical Uricometer.—Dr. William Weinberger demonstrated this apparatus which permitted the estimation of uric acid in as little as one drop of blood serum. He said that the principle of the method consisted in comparing the stain produced by the appearance of silver urate on a strip of filter paper, which was impregnated with a solution of silver nitrate, with the color tints of a colorimetric scale furnished with the apparatus. Strips of silver nitrate paper, two bottles, one containing concentrated ammonia, the other a solution of sodium carbonate, a dozen tiny test tubes for the reception of the ten to fifteen drops of blood needed, a number of capillary pipettes and the colorimetric scale comprised the whole apparatus. This method had to recommend it the following points: (1) The small amount of blood needed, which could easily be obtained from the finger tip, especially if the arm be temporarily constricted by means of a rubber tube or an ordinary gauze bandage—as against from 15 to 25 c.c. of blood needed for the modern method Folin's; (2) The simplicity of the method, which requires no chemical skill at all; (3) The quickness with which results were obtained in that the actual working time does not exceed a few minutes; (4) The relative accuracy, which was sufficient for clinical purposes to allow the recognition of larger amounts of uric acid (above 7 mgm. in 100 c.c. blood). However, the apparatus did not with any degree of accuracy indicate the complete absence of uric acid—on account of the inevitable darkening of the silver nitrate paper—nor could the results obtained in any way be relied upon in cases of moderate uricemia—the tint obtained if less than 7 mgm. of uric acid were present in 100 c.c. of blood, not being sharp enough. Further there might be mentioned the necessity of conducting the manipulations in the dark room—to avoid the spontaneous darkening of the silver paper. In summarizing it might be said that the quick method of estimating the uric acid in small amounts of blood by means of this apparatus, while not accurate enough for exact quantitative estimations in all cases of suspected uricemia, would be found of sufficient accuracy to establish the presence of large amounts of uric acid in the blood (7 or more mgm. in 100 c.c. of blood). The apparatus might be recommended to the clinician for preliminary purposes only; it could not supplant the more accurate scientific methods.

Blindness in an Infant as a Result of Facial Eczema.—Dr. Sidney V. Haas reported this case, which, so far as he could ascertain from a search of the literature, was unique. The patient, an infant five months of age, was admitted to the Lebanon Hospital on March 8, 1914, with characteristic severe facial eczema, involving the face and scalp with scattered small areas on the extremities. Shortly after admission this process involved the eyes. A panophthalmitis followed with complete loss of sight. The child gave a history of having had three previous attacks of facial eczema during the two and one-half months preceding its admission to the hospital. The present attack began two weeks before admission and differed from the others in that the eruption appeared over the entire face at the same time instead of beginning at a point and spreading. Physical examination showed the skin dry, scaly over the entire left side of the face and the greater part of the right side, and also over the scalp. There was a papular erythema upon the external aspects of both elbows and upper portion of the forearms and also over the anterior aspects of both legs. There was a slight eruption over the buttocks. A slight general adenitis was present, most marked in the cervical region and the angle of the jaw. The eyes appeared to be normal, and the physical examination was negative in other respects. On the day of admission the temperature ranged between 99° and 100.6° F. On March 10, two days after admission, the temperature rose to 105.4°, pulse 140, and respirations 48, for which no cause could be assigned except the skin lesion. The temperature throughout the child's stay in the hospital ranged irregularly between 98.6° and 104.4°, presenting no regularity and no type. The pulse ranged from 100 to 160 and the respiration from 26 to 56. Examination of the urine and blood showed nothing of particular interest. After a week's stay in the hospital the eyelids were slightly edematous and covered with eczema. The discharge from the conjunctival sac became profuse, and examination on March 18 showed the presence of *Staphylococcus pyogenes aureus*. Examination of the eyes on March 23 showed deep corneal ulcers with lesion of the cornea. The discharge from the eyes and the edema of the lids increased and examination of the eyes on March 23rd showed deep corneal ulcers with strings of yellowish secretion and infiltrated. The anterior chamber was abolished. At the external canthus of the eyes where the discharge flowed over the skin there was distinct erosion of the integument. A second culture taken from the conjunctival sac showed *Staphylococcus pyogenes aureus* and the pneumococcus. On April 1 the child was taken home by its parents and died twenty-four hours later. The treatment while in the hospital consisted in a reduction of the quantity of milk taken by the mother and in the time and frequency of nursing, the use of atropine 1-1,000 internally, beginning with one drop to be increased one drop every other day, colonic irrigations of bicarbonate of soda solution, olive oil dressings to remove the crusts, followed later in sequence by one per cent. salicylic acid in olive oil, liquor burrowi, and a mixture of zinc oxide 15.00, carbolic acid 4.00, and lime water 500.00. Dr. Jacob Sobel saw the child on the day after its discharge from the hospital. He found a double panophthalmitis, eyeballs grayish yellow, erosion at the canthi, but no other physical signs, though the child was almost moribund. This case of eczema was in no wise different in external appearance from those so frequently seen and gave no hint of the tragedy that was to follow unless the irregular temperature which ranged somewhat higher at times than was usual could be so construed, and for which no other explanation could be found excepting absorption from the large area involved in the pathological process. The eyes became involved and destroyed in a manner which could only be described as fulminant. The microorganisms apparently responsible were the *Staphylococcus pyogenes aureus* and the pneumococcus, death following from asthenia as a result of the sepsis.

Lymphatic Leucemia without Demonstrable Lym-

phatic Enlargement.—Dr. Herman T. Radin made this report. The patient, 26 years of age, married, was admitted to the Lebanon Hospital, October 3, 1914. Her illness began about five months before admission with pain in the upper part of the thigh, mostly at night. This pain would disappear in the morning. The pain occurred first in one thigh, then in the other and sometimes in both. Afterward the pain involved the hip. The patient was treated by several physicians who said she had multiple neuritis. During the past few months she had been getting paler and complained of pains all over the body. There was no interference with motion. The physical examination showed marked pallor of the face and the mucous membranes were anemic. Examination of the chest and abdomen was negative except for a slight enlargement of the spleen, which was palpable about one inch below the costal margin. There was distinct tenderness over both hips, some tenderness over both femurs, and also over both humeri. The lymphatic glands were nowhere pathologically enlarged. The blood examination showed: hemoglobin, 50 per cent.; red blood corpuscles, 2,200,000, white blood corpuscles, 30,000. Differential count: Polymorphonuclears, 16 per cent.; small lymphocytes 69 per cent., large lymphocytes 13 per cent. Two days later the large lymphocytes were 15 per cent.; small lymphocytes 80 per cent.; total lymphocytes 95 per cent. The lymphocyte count remained around 90 per cent. for several weeks, and never went below 75 per cent. The total leucocyte count rose to 50 per cent. After treatment by benzol the leucocytes went down from 50,000 to as low as 13,000. The patient was often entirely free from the pains in the long bones, but these would recur every few days. The patient also complained of pain in the lower jaw, often very severe. Later she developed severe pain in the arms as well as the legs. Dissatisfied with the treatment because the pains recurred, she left the hospital after about eight weeks and sought treatment elsewhere. The patient had since died. During her entire stay in the hospital she developed no pathological enlargement of the lymphatic glands which was almost always found in the lymphoid form of leucemia. The extreme pallor and the pains in the long bones indicated changes in the bone marrow and should have suggested the possibility of leucemia and the desirability of making a blood examination which would have revealed the diagnosis immediately, but no such examination was made until the patient was admitted to the hospital.

Philadelphia Neurological Society.

At a stated meeting held February 26 Dr. Williams B. Cadwalader presented a report of "Three Cases of Pseudosclerosis Occurring in the Same Family." The patients were brothers, while two sisters apparently escaped the disease. The principal symptom was tremor in various parts of the body and of dissimilar distribution in the several cases. In many respects the cases bore a resemblance to those of lenticular degeneration described by Kinnear Wilson and others, and it was pointed out that further observation may show that the two disorders are in reality one and the same.

Dr. Harry B. Wilmer exhibited by invitation "A Case of Thalamus Lesion." The patient was a man, about sixty years old, who without warning became unconscious and later exhibited paralysis of the left upper and lower extremities of transitory character. The weakness in the lower extremity disappeared almost entirely, while that in the upper extremity was inconsiderable. There was some defect of tactile sensibility in the left hand, associated with astereognosis, and pain was developed in the left upper extremity on active exercise of the part. The reflexes were unchanged, and the fundus oculi presented no abnormality.

Dr. Alfred Gordon reported "A Case of Right Hemiplegia with Aphasia Unattended with Intellectual Deficit." The patient understood everything that was said to him and he recognized objects clearly, but he was wholly unable to give verbal expression to ideas. The case was, therefore, one of purely motor aphasia, with preservation of intelligence.

Drs. Theodore H. Weisenburg and Philip Work presented a communication entitled "The Distribution of Tabetic Crises," and they exhibited an illustrative case of an unusual character. The patient was a miner, about twenty-eight years old, with a syphilitic history and positive blood-serum Wassermann reaction and a less actively positive spinal fluid reaction. While under treatment in a hospital he was seized with vomiting, in conjunction with the presence of other symptoms of gastric ulcer, and for the relief of which operation was undertaken, the stomach being found normal and a healthy vermiform appendix being removed. On further examination it was found that, while the knee-jerks were present, station and gait were unsteady, the pupils unequal though reactive to light and in accommodation, while there was an area of hypesthesia on the front and back of the chest corresponding to the distribution of the fourth, fifth and sixth thoracic nerves. Accordingly, the case was looked upon as one of syphilitic posterior spinal sclerosis of circumscribed extent, attended with gastric crises.

Dr. Fred. W. Weidman presented by invitation a specimen of "Ruptured Aneurysm of the Left Vertebral Artery." The patient was a sailor who was suddenly seized with a chill, vomiting and loss of consciousness. After a time consciousness returned, but after a short interval it was again lost and opisthotonic rigidity developed. Death resulted and on post-mortem examination an aneurysm of the left vertebral artery was found which had ruptured into the cerebrospinal sac. Histologically the formation was found to present the characters of a dissecting aneurysm. Atheromatous changes were found in various parts of the vascular system.

Dr. Weidman exhibited also a specimen of traumatic separation of the cord and brain in a babboon. The accident occurred in the local Zoological Garden where the head of the small animal was caught by the paw of a larger and vicious monkey and drawn violently through the bars of the cage. The head of the smaller animal was almost pulled away from the body, the two parts being held together only by the soft tissues.

Dr. Charles W. Burr exhibited "A Brain Showing a Tumor of the Cerebellum." The specimen came from a man who, previously enjoying a fair measure of prosperity in a foreign country, had come to the United States and suffered loss and privation. As a result he had attempted to commit suicide and for this reason he was admitted to the psychopathic ward of the Philadelphia General Hospital. Here he presented few symptoms for awhile, but gradually he developed deafness with loss of vision, and evidences of mental deterioration. Examination of the eyes disclosed the presence of a papilledema, with edema and hemorrhages. With a view to the possible amelioration of the ocular conditions decompressive trephining was undertaken. The brain was forcibly extruded through the opening made, but no relief ensued, and in a short while death resulted. On post-mortem examination a tumor of considerable size was found in the left cerebellopontile angle. It was pointed out that probably there was no relation between the patient's acts and his mental state on the one hand and the presence of the neoplasm on the other hand.

Dr. Isaac H. Jones presented a communication entitled "Ear-Examinations to Aid Intracranial Localization. Report of Eight Operations; one Autopsy. Brain Showed that Ear-tests had Correctly Localized Cerebellar Tumor." By douching the ear with hot or with cold water and by rotating the patient rapidly in a suitable chair certain responses were obtained with respect to the direction in which one or the other hand was pointed, or with respect to the development of nystagmus and its direction, that had been found to be indicative of the preservation or absence of the reflex arc between the labyrinth of the ear and the cerebellum. Such observations carefully made and thoroughly carried out had been found to be of much use in the establishment or confirmation of the existence of cerebellar disease of one sort or another and thus to lead to successful operative intervention.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

June, 1914.

(*Continued from page* 462.)

PATHOLOGY.

1. How would you estimate the number of bacteria present in a given amount of liquid, for instance, in 1 c.c. of milk?

2. Tenia solium. Describe it and give its life history

3. Describe the changes occurring in and following fibrinous or plastic pleurisy.

4. How is typhoid fever transmitted? How in general is it prevented? On what does its specific prevention depend?

5. Describe the precipitin reaction. Of what medico-legal importance is it.

6. What is a thrombus? An embolus?

7. Describe the changes occurring in untreated gonorrheal ophthalmia.

8. Describe an "adenoid." When may adenoid tissue be considered pathological?

9. How are specimens for microscopic examination made by the freezing method.

10. What is an abscess? Describe the processes of its production.

PRACTICE.

1. Define: (*a*) Epistaxis, hemoptysis, hematemesis. (*b*) Anuria, polyuria, hematuria. (*c*) Pellagra. (*d*) Pertussis. (e) Litten's sign. Romberg's sign.

2. Define: (*a*) Koplik's sign. Kernig's sign. (*b*) Anterior poliomyelitis. (*c*) Percussion, auscultation, vocal fremitus, succussion. (*d*) Emphysema. (*e*) Urticaria.

3. Differentiate: Rubeola, scarlatina, and rubella.

4. What diseases are most commonly found in the right iliac region?

5. Name the various types of organic valvular heart disease.

6. Give fully the differential diagnosis between cholelithiasis and nephrolithiasis.

7. Name the various diseases in which dysphagia occurs.

8. Give treatment of scarlet fever and its complications.

9. Give treatment of ulcerative stomatitis.

10. Give treatment of typhoid fever and its principal complications.

ANSWERS.

PATHOLOGY.

1. *To estimate the number of bacteria in milk:* "Make a known dilution of the milk with sterile water; add definite quantities of this diluted milk to tubes of melted agar or gelatin and pour into plates. The diluted milk may also be delivered in the center of the plate and the melted agar or gelatin poured directly on it, mixing thoroughly. Always shake the bottle well before taking sample. Example: Add 1 c.c. of milk to 199 c.c. of sterile water in a large flask (500 to 1,000 c.c.). After shaking thoroughly, take 1 c.c. of this 1:200 dilution and add it to 99 c.c. of sterile water. Shaking thoroughly, we have a dilution of 1:20,000. Of this we added .5 c.c. to a tube of gelatin or agar. After incubation the plate showed 75 colonies. Therefore the milk contained in each c.c. $75 \times 2 \times 20{,}000$ (dilution) $= 3{,}000{,}000$—the number of bacteria in each c.c. of milk."—(Stitt's *Bacteriology.*)

2. TÆNIA SOLIUM. *"General characters.*—The adult worm or strobila measures about two to ten feet in length. It has a small head, long narrow neck, and transversely segmented body. The head is small, rounded, about the size of a pinhead, and consists of a rostellum or beak with twenty-six hooklets, and of a wider part on which are four suckers. Next the head comes a long, narrow, thread-like neck, followed by a series of larger segments—the proglottides. The first segments are broader than they are long, and are immature. The remaining segments are the reverse, longer than broad, and are sexually mature proglottides. These proglottides are hermaphrodite, the genital orifices being placed alternately on each side of the body, and the male and female organs open by this common genital pore. They have a complete water-vascular system. The uterus consists of a central stem, with seven to ten lateral branches on either side, each of which again branches. The testes appear as clear, white, convoluted tubes, with vesicles. The ova are nearly spherical in shape, about 1/750 inch in diameter, and are surrounded by a dense capsule which encloses the partly-developed, six-hooked embryos. In the flesh of the pig these embryos give rise to the scolices, which are known as 'measles,' cysticerci, or bladder-worms.

"Life history.—As above described. Intermediate host—the pig, which gets the embryos from water—the scolices forming the 'measles' of pork. Within these measles or cysts, the hooklets, which do not decompose, are often found after the scolex has perished. They are short, broad, hook-shaped bodies, with a small knob at their base. Host—man; owing to eating imperfectly cooked, measly pork. The parasite infests man, not only as the mature worm, but as cysticerci. The adult worm is found in man only. Habitat.—The immature worm is found in the subcutaneous tissues, muscle, brain, eye, and liver of the pig; the mature form, in the small intestine of man."—(Wheeler and Jack's *Handbook of Medicine.*)

3. *Fibrinous or plastic pleurisy.*—"The lesions may be more or less diffuse, but they are usually circumscribed, especially to the base of the lungs anteriorly and laterally, but often also at the apex (frequently overlooked). The inflamed area becomes hyperemic, swollen, lustreless and finally granular in appearance; and the seat of a more or less abundant thick or thin, usually slightly adherent fibrinous exudation. In reality the exudation is serofibrinous, that is, there is always some fluid exudation, but this is often minimal (dry pleurisy), and the excess of fibrin causes agglutination of the opposed pleural surfaces. Ultimately the exudation undergoes organization with the formation of permanent adhesions and pleural thickening."—(Kelly's *Practice of Medicine.*)

4. Typhoid fever is transmitted by contaminated water, ice, or milk; shellfish; stools and urine of the patient; flies, and "typhoid carriers." Its specific prevention depends on the use of the prophylactic vaccine.

5. "The phenomenon of *protein precipitation* is absolutely analogous to that of bacterial precipitation. If a clear proteid solution (*a*) is mixed with the clear serum (*a'*) of an animal immunized against the above proteid (*a*), turbidity and precipitation will occur; while if a mixture of the serum (*a'*) is made with a non-homologous proteid, say (*b*), or a mixture of the proteid (*a*) with the serum (*b'*) of an animal immunized against (*b*), no precipitation takes plaec. Graphically expressed it looks thus:

$a + a' =$ precipitation.
$b + a' =$ no precipitation.
$a + b' =$ no precipitation.
$b + b' =$ precipitation.

In other words, a precipitating immune serum reacts only with its homologous proteid. The precipitin reaction is specific.

"Medico-legal value.—For example, a bloody shirt is found in the home of a man charged with murder; the prosecution sees in that the proof of crime, while the defendant pleads that the stains belong to the blood of a sheep; the proof as to their source is of the utmost deciding evidence; and while chemical or microscopical examinations are of little or no use, serum diagnosis wins the day. The blood-stained clothing is extracted in water, part of the extract is mixed with *a*, the serum of a rabbit immunized against human serum, and another part is mixed with *b*, the serum of a rabbit immunized against sheep's serum. If the mixture *a* shows a precipitate, it can be definitely stated that the blood stain contained serum derived from a human being; while if mixture *a* is clear and *b* shows the precipitate, it is strongly corroborative of the presence of sheep's serum."—(Citron's *Immunity.*)

6. *Thrombus* is a blood-clot formed within the heart or blood vessels during life.

Embolus is a clot or other substance brought by the blood current, and forming an obstruction where it lodges.

7. *Gonorrheal ophthalmia.*—"The disease, if untreated, declines spontaneously, and the discharge almost ceases in about six weeks, the palbebral conjunctiva being left thick, relaxed, and more or less granular. Cicatricial changes, identical with, but less severe than those resulting from chronic granular lids, and analogous to those which occur in stricture of the urethra, sometimes follow; considerable permanent thickening of the ocular conjunctiva may also occur. There is a great risk to the cornea in this disease, partly from strangulation of the vessels, partly from the local influence of the discharge. If within the first two or three days the cornea becomes hazy and dull, like that of a dead fish, there is great risk that total or extensive sloughing will occur. In many of the milder cases ulcers form a little below the center, and rapidly cause perforation. In other cases clear, deep ulcers form close to the edge of the cornea. There is less risk of ulceration of the cornea in the purulent ophthalmia of infants than in that of adults. Either one or both eyes may be attacked; in adults one eye often escapes; in infants, where the inoculation occurs during birth, both eyes almost always suffer."—(Nettleship's *Diseases of the Eye.*)

8. An adenoid is an overgrown form of lymphatic

and connective tissue, found in the posterior wall of the pharynx. Adenoids may be considered pathological when they interfere with breathing or any other normal function, or cause any abnormal condition such as snoring.

9. "The piece of tissue used should not be more than 4 mm. high and it must be free from all traces of alcohol. The alcohol is removed by placing the specimen in a large amount of water that is of a temperature of about 30 deg. C. The specimen is placed on the metal stand and a spray of ether or of carbonic acid gas is directed against the under side. The tissue is held in place by lightly pressing upon it with some flat piece of wood, as the handle of a small scalpel. Care must be taken not to freeze the tissue too hard or it will be so brittle as to break or show irregular streaks. The cut sections should be placed in 80 per cent. alcohol, as they will unroll better than if put directly into water." —(McConnell's *Pathology.*)

10. An *abscess* is a localized collection of pus in a cavity of new formation. *Formation of an abscess.*—"When pyogenic bacteria are introduced into the tissues there ensues an inflammatory reaction, which is characterized by dilatation of the blood vessels, exudation of serum, migration of large numbers of leucocytes, and proliferation of connective-tissue cells. These wandering cells soon accumulate around the focus of infection, and form a protective barrier which tends to prevent the spread of the organisms and to restrict their field of action. Within the area thus circumscribed the struggle between the bacteria and the phagocytes takes place, and in the process toxins are formed by the organisms, a certain number of the leucocytes succumb, and, becoming disintegrated, set free certain proteolytic enzymes or ferments. The toxins cause coagulation-necrosis of the tissue cells with which they come in contact, the ferments liquefy the exudate and other albuminous substances, and in this way pus is formed. If the bacteria gain the upper hand, this process of liquefaction, which is characteristic of suppuration, extends into the surrounding tissues, the protective barrier of leucocytes is broken down, and the suppurative process spreads. A fresh accession of leucocytes, however, forms a new barrier, and eventually the spread is arrested, and the collection of pus so hemmed in constitutes an abscess."—(Thomson and Miles' *Surgery.*)

PRACTICE.

1. *Epistaxis* is hemorrhage from the nose.

Hemoptysis is spitting of blood, from the respiratory tract.

Hematemesis is vomiting of blood, from the stomach.

Anuria is suppression of urine.

Polyuria is the discharge of an excessive quantity of urine.

Hematuria is the discharge of urine containing blood.

Pellagra is a disease, probably of protozoan origin, and characterized by erythema, gastrointestinal disturbances, and nervous and mental symptoms.

Pertussis is whooping cough; *i.e.* a communicable disease characterized by a catarrhal inflammation of the air passages and paroxysms of coughing which terminate with a peculiar loud whooping inspiration.

Litten's sign is retraction of the side of the thorax at the insertion of the diaphragm; it is absent in pleuritic adhesions, emphysema, etc.

Romberg's sign is the swaying of the body and inability to stand when the eyes are closed and the feet are placed together; observed in locomotor ataxia.

2. *Koplik's sign or spots*, small bluish-white spots surrounded by a reddish areola, seen on the mucous membrane of the mouth in the prodromal stage of measles.

Kering's sign: With the patient lying on his back and the thigh flexed at right angles with the trunk, extension of the leg on the thigh is impossible; observed in meningitis.

Anterior poliomyclitis is inflammation of the anterior cornua of the spinal cord.

Percussion is a means of physical diagnosis; by striking or tapping on a part the condition of the underlying parts is ascertained by the sound produced.

Auscultation is a means of physical diagnosis; it consists in listening to the sounds produced in some internal part of the body.

Vocal fremitus is the thrill conveyed by the hand placed on the chest during speaking.

Succussion is the shaking of a person from side to side with the object of determining the presence of fluid in a cavity or hollow organ.

Emphysema is the presence of a gas in a tissue that is normally free from it; or excess of a gas in a part that normally has some of it.

Urticaria is a condition of the skin characterized by wheals which cause a burning and itching sensation.

3. *Scarlet fever.* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Rubeola. Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

Rubella. Period of incubation, ten to seventeen days. Stage of invasion one day. Eruption appears on first day, is most intense on second day, consists of red papules. Often fades from face before it is seen on the limbs. The pulse is not much accelerated, all the symptoms are slight. Desquamation is very slight. There may be slight sore throat and swollen cervical glands. Koplik's spots are absent.

4. In the *right iliac region*, there may be found: Appendicitis, psoas abscess, inguinal hernia, fibroid tumor, ovarian abscess or cyst, hematoma, cancer of cecum, intussusception, pyosalpinx.

5. *Organic Valvular Heart Disease.* May be: Aortic regurgitation, aortic stenosis, mitral regurgitation, mitral stenosis, tricuspid regurgitation, tricuspid stenosis, pulmonary regurgitation, pulmonary stenosis, or various combinations of these.

6. In *cholelithiasis*, the attack is sudden; the pain very severe, and generally localized in the right hypochondriac region and often spreading to right scapula and over the abdomen; vomiting, chill, fever, drenching sweats, feeble and rapid pulse are common; liver and gall-bladder are swollen and tender; jaundice may supervene; the urine may show bile pigment and albumin; examination of the feces for a few days after the attack may reveal the calculus.

In *nephrolithiasis*, the pain is also sudden and very severe, begins in the lumbar region and follows the course of the ureter, and is often referred to the testicle and glans penis; nausea, vomiting, chills, fever, and sweat are common; strangury may be present; there is great prostration following the attack; there may be polyuria or suppression of urine; with the aid of a cystoscope or sound, the calculus may be found in the bladder; examination of the feces is negative.

7. *Dysphagia may occur in:* Glossitis, tumor of tongue, stomatitis, tonsillitis, pharyngitis, retro-pharyngeal abscess, diphtheria, paralysis or spasm of the palate or pharynx, laryngitis, cancer or ulcer of the larynx, spasm or inflammation of the esophagus, enlarged thyroid gland, thoracic aneurysm, enlarged bronchial glands, lymphadenoma, mediastinal tumors, and large pericardial or pleural effusions.—(From Butler's *Diagnostics of Internal Medicine.*)

8. *Treatment of scarlet fever and its complications.* The treatment is that of infectious fevers in general, and in addition: "1. *Serum treatment.*—Serum from convalescents, injected in doses up to 20 c.c., has sometimes proved successful. Good results have also been obtained with polyvalent antistreptococcic sera (*i.e.* sera prepared from several different strains of cocci). 2. The danger of spreading the disease is greatest during the desquamative period. Isolation must therefore be kept up for at least six weeks from the onset, or till all desquamation and discharges (nasal, aural, etc.) have ceased. 3. A minimum amount of nitrogenous food, to avoid irritation of the kidneys. This caution does not affect milk, which may be freely used. 4. Daily toilet, tepid sponging, or tepid baths. 5. Inunction of oily antiseptic preparations into the skin, to prevent dissemination of the desquamating scales. 6. Examine the urine daily for signs of nephritis. 7. The condition of the ears must also be very carefully watched.

"*Complications.*—*Arthritis* demands warm and sedative applications. Wrap the joints in cotton wool; alkalies

are better than salicylates, as the latter tend to irritate the kidneys. *Throat.*—Ice to suck; antiseptic sprays; glycerin of carbolic acid; warm applications externally.

"*For the severe types.*—Avoid caustic applications; relieve pain by cocaine solutions; internally, tincture of ferric chloride, with free administration of ammonia; quinine, either alone or with ferric chloride. Stimulants may also be required. Nasal feeding often gives much relief. *Nephritis.*—Milk diet, hydragogue purgatives (avoid mercurials), hot-air baths, hot packs, etc., according to the severity of the dropsy." (Wheeler and Jack's *Handbook of medicine.*)

9. *Treatment of ulcerative stomatitis:* Nourishing food in fluid form; potassium chlorate, gr.x, t.i.d., internally, and also as a mouth wash; nitrate of silver may be applied to the ulcers; the mouth must be kept as clean as possible.

10. *Treatment of typhoid fever with its principal complications:* The patient must be in bed, and no medicine given unless indicated. "Give no solid food, or that which would not readily pass through a fine sieve. Milk, if it agrees, albumin-water made from white of egg, beef tea, and chicken broth are the principal foods. Of late some authorities have advocated a light solid diet throughout, but nothing must be given that would increase the risk of perforation. The stools should be daily inspected. If undigested curd is found, milk is being given too often, or the gastric function is impaired. It may then be given with lime water or barley water. Beef tea should be sparingly used, lest it excite diarrhea. Alcohol is required mainly in the later stages, when the typhoid state has set in, and the heart is weak. Many cases do well without it altogether. Other stimulants are strychnine, ammonia, ether, etc.

"If the *diarrhea* becomes excessive give bismuth and opium, or lead acetate and morphia, or an enema of starch and opium. When the motions are very offensive intestinal antiseptics (calomel in small doses, salol, etc.), may be given. They are also useful in meteorism. If *constipation* be troublesome, give enemata. No purgatives should be given after the first week. *Hemorrhage*—opium, lead acetate, or calcium lactate gr. xv every four hours, hypodermic injection of morphine or ergotin, and the application of an ice-bag to the cecum.

"*Perforation.*—The main chance of recovery lies in early laparotomy and suture of the affected bowel. Every hour lost after the diagnosis is made, and the initial shock has passed off, increases the danger to life. Patients operated on within twenty-four hours may recover; later, recovery is very rare. In anticipation of operation, morphine may be given to relieve pain and diminish peristalsis. *Bed sores*—water-bed, cleanliness, stimulant and antiseptic lotions, dry dressings if the slough is large. *High fever*—quinine and cold baths. The antipyrin group is dangerous to the heart. The stools and urine must be carefully disinfected. During *convalescence* the diet must be increased with the utmost caution, and the possibility of relapse must always be remembered." (Wheeler and Jack's *Handbook of Medicine.*)

(*To be continued.*)

Multiple Exostoses.—P. Turner reports the cases of a boy aged thirteen years who had a painful swelling at the inner end of the right clavicle. This proved to be an exostosis, the pain being probably due to some slight injury. Examination showed the presence of bony outgrowths near the extremities of most of the long bones. Of special interest was a very large growth from the outer surface of the left ilium and a small exostosis apparently growing from the lamina of one of the dorsal vertebræ. The bones of the hands and feet were not affected. The tumors gave rise to no symptoms and caused no disability. The boy's father, a rather small but muscular man, aged about thirty-five years, also had multiple bony tumors which he said had been present since infancy. He also had a large exostosis growing from the outer surface of the left ilium, and two very large masses attached to the lower extremity of the left femur, as well as numerous smaller exostoses growing from other bones. In his case the bones of the hands and feet were normal, and the tumors caused no inconvenience. There was no history of similar tumors in any other members of the family.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

Treatment of Tabetic Pains.—Müller is said to recommend intramuscular injections of the following solution in the treatment of the pains of tabes:

℞ Thiosinamine, 1 gram.
Glycerin, 1 gram.
Sodium salicylate, 2 grams.
Sterile distilled water, 10 cubic centimeters.

M. Sig.: One cubic centimeter should be injected daily or on alternate days.—*La Riforma Medica.*

A Stomachic for Children.—L. Freyberger cites the following from the formulary of the Great Ormond Street Hospital, London:

℞ Sodium bicarbonate, gr ij.
Spirit of chloroform, ℥ij.
Compound infusion of gentian, ʒj.

M. Sig.: Three time a day.—"Pocket Formulary for the Treatment of Disease in Children."

Treatment of Emphysema and Chronic Bronchitis.—E. Müller recommends the following:

℞ Anisated solution of ammonia.
Tincture of stramonium.
Tincture of opium, āā 5 grams.

M. Sig.: Fifteen to twenty drops in water three times a day.—"Die Therapie des praktischen Arztes."

Management of Chronic Alcoholic Gastritis.—Oettinger prescribes scale pepsin in doses of one-half gram in cachet after meals, together with tablespoonful doses of the following mixture:

℞ Dilute hydrochloric acid, 3 grams.
Syrup of lemon, 100 grams.
Distilled water, 200 grams.

—*Gazzetta degli Ospedali e delle Cliniche.*

Drug Treatment of Pneumonia in Children.—H. W. Dana prescribes the following mixture for an eighteen-months-old baby:

℞ Ammonium chloride, ʒj.
Syrup of ipecac, ʒjss.
Tincture of belladonna, ʒj.
Fluid extract of licorice, ʒvss.

M. Sig.: Give eight drops in a teaspoonful of boiled water every two hours.—*Boston Medical and Surgical Journal.*

The Rapid Sterilization of Water.—R. R. Mendez cites the following method which has been devised by G. Lambert-Forment. The organic matter and the bacteria are destroyed by the addition to each liter of water of the following powder:

℞ Potassium permanganate, 0.05 gram.
Manganese dioxide, 0.05 gram.
Powdered talc, 0.37 gram.
Calcium carbonate, 0.02 gram.

At the end of ten minutes the excess of permanganate is neutralized by the addition of 0.06 gram of hyposulphite of soda and 0.44 gram of powdered talc. The supernatant liquid is then decanted off and filtered.—*Revista Médica de Sevilla.*

Treatment of Comedones.—L. Pron states that Brocq and Simon recommend the following method: Every eight or ten days after a thorough scrubbing of the face, the comedones are expressed by means of a suitable instrument, as a watchkey, and then cologne water is applied to the face, after which the lesions are treated with the following solution:

℞ Salicylic acid, 1 gram.
Green soap, 40 grams.
Tincture of lavender, 10 grams.
Alcohol (90 per cent.), 80 grams.

If the latter is too irritating it may be diluted. —"Formulaire de Thérapeutique Clinique."

THE RELATION OF HERNIA TO THE WORKMEN'S COMPENSATION LAW.*

By ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ATTENDING SURGEON, MT. SINAI HOSPITAL; VISITING SURGEON, HARMORIAH HOSPITAL.

In 1914 the Legislature of the State of New York passed Chapter 67 of the Consolidated Laws, known as the "Workmen's Compensation Law." By the terms of this law, workingmen, engaged in certain hazardous employments, are entitled to compensation for injuries sustained or death incurred, in the course of their occupation. In most instances the injury is so manifest that there is no question of the validity of the claim, and in consequence the duties of the commission are comparatively easy, consisting merely of a weighing of the evidence, and the decision of the amount to be awarded. In some instances, however, the injury is not so manifest; unjust claims for injuries are sometimes made by dishonest persons; important as these cases are, both from a medical and legal point of view, I cannot enter into their discussion at the present time. I am more interested at present in a third possibility; namely, that a claim is made in perfectly good faith for a "malady," which in the mind of the claimant was the result of an injury, but which, as I shall show, cannot be regarded as the result of a trauma. I refer to perhaps the most common instance of such claims, namely, hernia.

The question of the relationship of an injury to a hernia is not only a very important one, but also a most difficult one, and one which cannot be decided offhand. I have no hesitancy in stating that all laymen, and almost all medical men, would not look upon the question as a very intricate one, and would very promptly decide the relationship between injury and hernia in an affirmative manner. In casting my lot with the minority, it is important that I state at the very outset, that I have no ax to grind, that I have no particular case in mind, that I have no particular theory to prove; that not only am I very anxious not to lead you astray, but I am more than anxious not to lead myself astray; and that, while I am approaching my subject with preconceived notions, I do so in an entirely unbiased manner; and were my conclusions of a contrary nature, I would defend them just as warmly.

In taking this stand, I have deemed it logical first to describe very deliberately the formation of an ordinary hernia, acquired in the routine of everyday life; in which the question of law or the question of Workmen's Compensation does not enter. At a superficial glance this question appears to be very simple; on second thought, however, it will quickly become evident that this simplicity is only an apparent one. Indeed, it is not only difficult, but very complicated. This is amply proven by consulting the very voluminous literature appertaining to the subject, as we find that very long and acrimonious discussions have been waged since time immemorial, not only regarding the causations of hernia, but even more regarding the mechanism, and regarding the number, the quality and quantity of the forces which come into play, and even now are far from being settled or universally accepted.

I believe the principal difficulty arises from the fact that whenever a new theory was proposed an attempt was immediately made to bring under this one theory the entire pathology and pathogenesis of hernia, to the exclusion of all other possibilities. The pathology and pathogenesis of every hernia is made up of so many parts, for instance the anatomy of the hernial apertures, and hernial roadsteads, congenital malformations, the mobility of the surrounding peritoneum, the mobility of the hernial contents, the propelling forces, the resisting forces, etc., that it is hardly fair to expect any working hypothesis to cover all the points possible.

It may not be amiss to review these theories briefly.

1. The oldest theory as to the etiology of hernia was that there occurred a tearing of the peritoneum, and that the abdominal contents prolapsed through the defect in the parietal peritoneum, so created. The colloquial name of a hernia, "rupture," denotes the mechanism which was imagined to take place normally in the formation of a hernia, and is perhaps one of the reasons why claims for damages or compensation are so frequently made. It is very surprising that this theory should have persisted, even though only in the lay mind, despite the fact that Celsus, in his description of hernia, some two thousand years ago, described the most common form, as occurring without a tear in the peritoneum. Like many other truths in medicine this was forgotten, and for many centuries the theory that hernia was the result of a tear of the peritoneum held sway, and was not abandoned completely until late in the seventeenth century, when more opportunity was afforded for anatomical dissections. Since that period the theories upon hernia begin to come thick and fast.

2. This theory assumes that the intraabdominal contents, under pressure from some external source, tend to escape at a point which does not offer sufficient resistance.

3. This theory assumes that hernia is caused by an inadequate fixation of the abdominal viscera. This theory concedes the presence of weak areas in the abdominal wall, but in addition the claim is

*Read at a meeting of the Medical Society of the County of New York, February 23, 1915.

made that normally fixed viscera cannot prolapse through these areas. Certain observations made upon the operating table certainly tend to prove the validity of this theory; almost every surgeon has noted the fact that in operations for large herniæ, after the hernial contents have been reduced, it is always the same loop of intestine, or the same piece of omentum which tends to prolapse. It cannot be denied that nature has so disposed the intraabdominal contents that they have only a very slight mobility, just sufficient, let us say, for the vermicular action of the intestine; at the same time it is also true that a change in posture does influence materially the position of the intra-abdominal contents; thus, for instance, the omentum or small intestines will be much nearer the pelvis in a sitting or squatting position than in the erect. It should also be borne in mind that the very presence of a hernia, or better said the presence of contents in a hernia, tends to drag the intraabdominal fixations of the intestine still more out of place. In other words, we have arrived not at a good working theory, but at a vicious circle.

4. The saccular theory. This theory presumes a peritoneal prolongation in the nature of a hernial sac, into which eventually the intraabdominal contents find their way, without any additional force, and without any deficiency in the supporting or fixating mechanism of the viscera.

5. Roser's theory, that the hernial sac is dragged out by an outward growth of a lobule of properitoneal fat, held sway for some years, but has now been practically abandoned.

6. The congenital theory of hernia is the only one of comparatively recent date. This theory has been proposed by Hamilton Russell, and is certainly very alluring. According to this theory all inguinal herniæ are due to a faulty closure of the processus vaginalis peritonei, *i.e.* that process of the peritoneum which accompanies or even precedes the testis in its descent to the scrotum. No one denies the incidence of a hernia when the vaginal process has never become obliterated; this variety, however, forms only a small percentage of all herniæ. To explain the common and more frequent types of so-called "acquired inguinal hernia," Russell and his followers assume an "imperfect" closure of the processus vaginalis. The assumption is, that the process has become obliterated normally in the lower part, but the upper part persists and forms the starting point of a hernia. Definite proof of this contention is lacking. Were this the case, then we would also find at our operations for inguinal hernia that the sac would be intimately adherent at its distal extremity to the fibrous cord remaining after obliteration of the distal portion of the processus vaginalis. As a matter of fact, we find such an adhesion only in that exceedingly rare form of hernia which has received the name of "hernia into the funicular process." On the contrary, we find that the distal portion of the sac, in most cases, can be readily peeled off bluntly without any sharp dissection. The often quoted autopsy reports in which, particularly in young infants, smaller or larger peritoneal dimples are found, are by no means convincing. Personally I am of the opinion that it would be presumptuous and more than risky to decide offhand whether these dimples are congenital remains of the processus vaginalis or small acquired hernial sacs. Murray submits also many arguments in support of the congenital theory, not only for inguinal, but also for femoral and other types of herniæ. None of these arguments are, in my opinion, absolutely convincing. No one can deny the possibility of congenital saccules in the inguinal and umbilical regions, both regions so intimately connected with the embryological development of the fetus; but to make the broad assertion that all herniæ, even in those regions where no fetal structures ever pass through, are caused by congenital sacs, is, in the light of our present knowledge, unwarranted.

In many respects it is really regrettable that the congenital theory cannot be accepted as valid. It would terminate once and forever all discussions upon the subject; it would materially lighten many worries of workmen's compensation commissions; a claimant would be told that he had his hernia since birth, and therefore, it could not be due to any accident, and in consequence he was not entitled to any award; and last, but not least, it would have saved me considerable trouble in the preparation of this communication, and you considerable time in listening to it. It is a very simple matter to deny a theory, and it is, therefore, very easy for me to deny the validity of all the theories just enumerated. The question may then be asked what have I to offer in their place. I shall allay all misgiving at once by telling you that I have no new theory to offer; first, because there is no necessity for one; and secondly, because the theories I have mentioned have exhausted all the possibilities. Each of these theories contains a modicum of truth and, to my mind, a hernia is really the resultant of the most important factors in these theories.

7. Excepting a very rare form of sliding hernia, my definition of a hernia is the following: A hernia is a protrusion of an intraabdominal viscus into a preformed sac of peritoneum. If this definition is correctly scrutinized it will be found that the only essential part of a hernia is the sac. I am sure it does not require any lengthy argument to prove my contention, but I may be permitted to prove it by a simple example. An individual in the erect position has a hernia, which is composed of two parts, namely, hernial sac plus hernial contents; he now lies down, and the contents are reduced; he of course still has his hernia, although there are no contents within the sac. The same is true of an individual who retains his hernial contents by a truss. The sac being an essential *sine qua non*, it is incumbent upon us to carefully analyze the mechanism of the formation of the sac. If this is done we encounter the following possibilities:

Acquired Hernia.—Before explaining the first, and incidentally the most common, method of formation of a hernial sac, it is necessary for me to again call attention to certain fundamental anatomical principles, which exist, not only in every hernia, but in fact in every abdomen. These are:

1. That the entire abdominal parietes are lined by peritoneum. The only exceptions are a few isolated areas to which the suspensory ligaments of the viscera find attachment. (This parietal peritoneum is pushed outward when a viscus escapes from the abdomen, and, therefore, constitutes the sac of the hernia.)

2. External to the peritoneum, and separated from it only by more or less developed (or in some parts entirely absent) layer of "properitoneal fat," there is a very dense fascia, known as the "intra-abdominal fascia." This fascia has received dif-

ferent names, according to its anatomical location, *e.g.* the diaphragmatic fascia, lining the diaphragm; the iliac fascia, lining the iliac fossa; the pelvic fascia, lining the pelvis; the transversalis fascia, lining the transversalis muscle, etc. It is unfortunate that these various names have become prevalent because the diversity of nomenclature tends to obscure an otherwise simple matter. It must never be forgotten that this fascia forms one continuous layer.

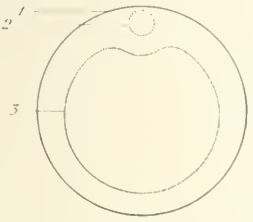

Fig. 1.—Section of the abdomen on a level above the bifurcation of the aorta, showing the relations of the aorta to the peritoneum and transversalis fascia. 1, Transversalis fascia; 2, aorta; 3, peritoneum.

The intraabdominal fascia is very dense and strong, but is stronger in some regions than in others. The strength of the intraabdominal fascia is of the greatest importance to the human economy, because at some areas of the abdomen it is, to all intents and purposes, the sole protective structure, and yet it serves its purpose so excellently that hernia at these points is of rare occurrence.

3. All the great vessels of the posterior abdominal wall lie upon the intraabdominal fascia, and are covered by the peritoneum. This fact is of fundamental importance to the proper understanding of the pathogenesis of every variety of hernia, and unless fully grasped all subsequent explanations are unintelligible.

Fig. 1 represents diagrammatically the relation of the vessels to the intraabdominal fascia and peritoneum, at any point above the bifurcation of the aorta. (For the sake of simplicity only the arteries are represented.)

At the point of exit of the femoral vessels into the thigh the diagram is modified as in Fig. 2.

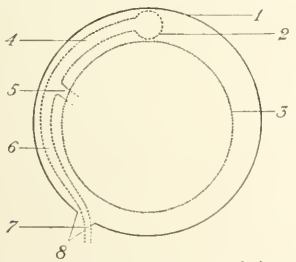

Fig. 2.—Section showing the relations of the aorta, common, external and internal iliac, and femoral arteries to the peritoneum and transversalis fascia. Note the hole in the transversalis fascia, through which the external iliac artery escapes to the thigh. 1, Transversalis fascia; 2, aorta; 3, peritoneum; 4, common iliac artery; 5, internal iliac artery; 6, external iliac artery; 7, femoral artery; 8, hole in the transversalis fascia.

Fig. 3 is a modification of Fig. 2, and represents similarly the exit of the spermatic vessels.

If Fig. 2 and Fig. 3 are examined it becomes evident that at the point where these vessels lose their relationship to the peritoneum there is an opening in the intraabdominal fascia, in order to permit the escape of these vessels from the abdomen. If there were no opening the vessels could obviously never escape to the thigh or testis. Now this opening in the intraabdominal fascia is of the greatest importance to every hernia, for through

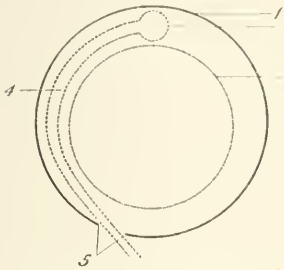

Fig. 3.—Section showing the relations of the aorta and spermatic artery to the peritoneum and transversalis fascia. Note the hole in the transversalis fascia, through which the spermatic artery escapes to the testis. 1, Transversalis fascia; 2, aorta; 3, peritoneum; 4, spermatic artery; 5, hole in the transversalis fascia.

it the hernia first escapes. In oblique inguinal hernia it is called the "internal inguinal ring"; in femoral hernia it is called the "internal femoral ring." Such an internal ring exists in every hernia.

The internal ring has been variously described by different anatomists. Its importance has always been appreciated, but the most important thing to remember about it is this: That it is merely a hiatus or hole in the intraabdominal fascia, and "only" in the intraabdominal fascia. The ring is surrounded by, covered by, and lies in close proximity to other structures, but as a hole it exists only in the intraabdominal fascia. Were this hole not present in the intraabdominal fascia the hernia could not occur at that particular site.

This hole, or internal inguinal ring in the present instance, can best be demonstrated from within the abdomen by raising the parietal peritoneum away from the intraabdominal fascia, thereby exposing the spermatic vessels as they enter the ring. It is slightly more difficult to demonstrate this structure by dissecting from without inward, because it is then necessary to make an artefact. The reason for this is that nature has put a nicer finish to this hole. Careful dissection will show that the intraabdominal fascia is continued downward for a certain distance upon the vessels, gradually be-

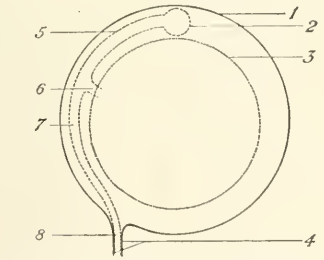

Fig. 4.—Section showing the relations of the aorta, common, external and internal iliac and femoral arteries to the peritoneum and transversalis fascia. Note the outward prolongation of the transversalis fascia upon the femoral artery, forming the so-called "sheath of the femoral vessels." 1, Transversalis fascia; 2, aorta; 3, peritoneum; 4, anterior and posterior prolongations of transversalis fascia, so-called "sheath of femoral vessels"; 5, common iliac artery; 6 internal iliac artery; 7, external iliac artery; 8, femoral artery.

coming thinner and thinner, and finally blending with the wall of the vessel itself. To be exact, therefore, the last two diagrams should be modified as in Figs. 4 and 5.

Now in certain areas these perivascular prolonga-

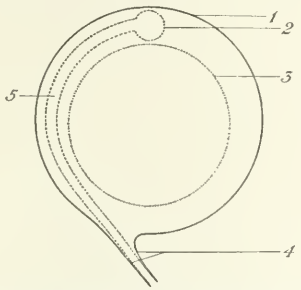

Fig. 5.—Section showing the relations of the aorta and spermatic artery to the peritoneum and transversalis fascia. Note the outward prolongation of the transversalis fascia above the spermatic artery, forming the so-called "infundibuliform fascia." 1, Transversalis fascia; 2, aorta; 3, peritoneum; 4, anterior and posterior prolongations of the transversalis fascia, so-called "infundibuliform fascia"; 5, spermatic artery.

tions of the intraabdominal fascia have been carefully studied, are well marked, and indeed, have received special names. I mention, for instance, the prolongation upon the spermatic vessels, which is called the "infundibuliform fascia"; and the prolongation upon the femoral vessels, which is called the "sheath of the femoral vessels."

A similar anatomical arrangement holds true for every blood vessel that escapes from the abdomen to the periphery; for instance, the obturator, or sciatic arteries, or the umbilical vein and arteries.

It is an established truth that the intraabdominal fascia, as a rule, is strong enough to retain the viscera within the abdomen. However, it is not strong enough to do so within certain definite anatomical areas, and it is at these areas, and at these areas only, that herniæ occur. A little reflection will show that herniæ occur only where blood vessels normally make their exit. It is apparent that these weak anatomical points are the attenuated perivascular projections of the intraabdominal fascia.

To return now to inguinal hernia in particular. It has just been pointed out that there exists naturally in the inguinal region a weak area in the in-

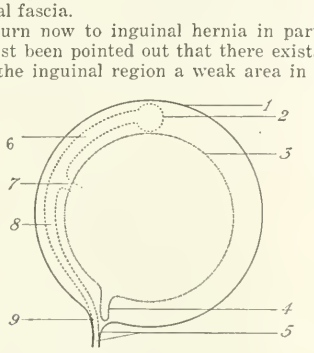

Fig. 6.—Diagrammatic illustration of a femoral hernia.

traabdominal fascia; and it is this weak area which determines the presence of an inguinal hernia.

At this point it may with propriety be argued that the anatomy just described exists in every individual, and yet only a certain percentage of these acquire an inguinal hernia. To combat these arguments we must turn our attention to the mechanical forces which come into play in a hernia. In every individual we must assume two forces to be constantly in action; one, the strength of the transversalis fascia, which tends to retain the intraabdominal contents within the abdomen; and the second, composed of a number of factors, namely, the intra-intestinal pressure, the abdominal muscles, the diaphragm and the muscles of respiration, which tend to propel the abdominal contents out of the abdomen. The latter force is not only constant, but is exaggerated to an extreme limit on some occasions. It would carry me beyond the limits of my time were I to enter into a description of these occasions; suffice it to say, that some are connected with physiological functions of the body, and some with our daily vocations.

Everything being normal we must also assume a perfect balancing between these two forces; and this being the case, no hernia will result. But let there be a disturbance in the exact balancing of these forces, *i.e.* let there be either a diminution of the restraining force or an increase in the propelling force, then the intraabdominal contents will tend to escape from the abdomen. Now this tendency is equally distributed throughout the entire abdomen, *i.e.* it is equal against all parts of the restraining force, *i.e.* the intraabdominal fascia. We

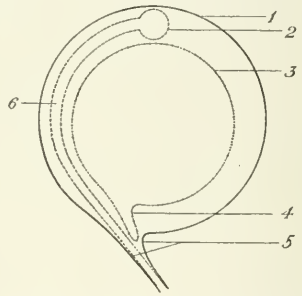

Fig. 7.—Diagrammatic illustration of an inguinal hernia.

have seen, however, that the intraabdominal fascia shows in certain locations of the abdomen weakened areas, preformed by the passage of vessels; it is not surprising, therefore, that the intraabdominal contents will find at these places inviting points of escape. These places are also protected by a layer of parietal peritoneum, and this parietal peritoneum is being pushed ahead of the escaping intraabdominal contents, in the form of a slight dimple. *This slight dimple is the beginning of every hernia.*

For a time everything is well, the propelling force having ceased the intestine resumes its normal anatomical position; the peritoneum also returns, and this I emphasize, it never again attains its normal conformation.

This is repeated time and again; more and more of the peritoneum is being pushed out, finally quite a fair sized sac is formed, until finally the intestine or omentum finds permanent lodgment within it. We now have a small, but nevertheless complete hernia. See Figs. 6 and 7.

The important points to remember in the formation of a hernia are two: First, the slight and insidious onset, and second, the slow growth. In other words, no fully developed hernia is ever acquired at the first insult, or at the first disturbance of the balance between the restraining and the propulsive forces. How soon thereafter a complete

hernia develops depends upon the frequency and magnitude of the increased propelling forces; in some cases it may take only days, in others it may last for years. The afflicted individual is only too prone to ascribe his hernia to one particular occasion, especially if he knows that a workingman's compensation award depends upon it. But you and I know that his hernia, which he may have only noted at that particular occasion, even if perfectly honest in his belief and statements, is only a culmination of many preceding insults, which may have antedated that occasion by years.

Finally we have also seen that the important part in the pathogenesis of hernia is the formation of the sac; and that the location of the hernia is entirely accidental, being proscribed by certain weak anatomical areas in the intraabdominal fascia.

The process just described is a crude, but nevertheless true outline of the manner in which an ordinary hernia is as a rule acquired. In addition there exist, however, a number of other factors which predispose an individual to the acquisition of a very common form of hernia, namely, the inguinal; these may be termed "contributing causes."

Contributing Causes. — 1. Certain Anatomical Peculiarities of the Inguinal Region.—If the inguinal region is viewed from within the abdomen there are to be seen three distinct elevations, separated by shallow, but nevertheless definite depressions. In the median line of the abdomen there exists the first elevation, caused by the presence of the urachus; to the outer side of the urachus is the first depression, the internal inguinal fossa. This is separated from the middle inguinal fossa by the second elevation, caused by the presence of the obliterated hypogastric artery. Finally, on the outer side of the middle inguinal fossa we have the third elevation, caused by the deep epigastric artery, to the outer side of which there is the third depression or external inguinal fossa, which corresponds to the internal inguinal ring. These shallow depressions, other things being equal, are preferred points for hernial incipiencies.

2. The Direction of the Inguinal Canal.—Roughly speaking, we describe as inguinal canal that portion of the inguinal region which is bounded internally by the internal inguinal ring (the hiatus in the intraabdominal fascia), and externally by the external inguinal ring (the hiatus in the aponeurosis of the external oblique). This canal in the normal individual has a definite length and width, and also a definite obliquity. In individuals afflicted with a hernia this normally definite length and obliquity are diminished, and the internal inguinal ring approaches the external inguinal ring; so that in herniæ of long standing the external and internal inguinal rings are directly opposite each other. But even in perfectly healthy individuals abnormalities occur in the direction, length, and width of the canal. While in a perfectly normal individual the internal inguinal ring is protected, for a while at least, by the overlying transversalis and internal oblique muscles; this is not the case in the short inguinal canals.

Incidentally, I may also add that I differ entirely from those observers who see in a large external inguinal ring a very important contributing cause to the development of hernia. I have already pointed out that hernia begins at the internal inguinal ring, and I, therefore, see no reason why any fault should be attached to the external inguinal ring. I will not deny the instrumentality of a large external inguinal ring in the later development of a hernia, but I do deny its instrumentality in the incipiency of a hernia. I have seen and followed for many years a number of individuals who upon first examination showed a very large external inguinal ring, and yet who never developed any hernia.

3. Varicocele and Veins.—By referring to Fig. 2 and Fig. 4 there will be seen a hiatus in the intraabdominal fascia, the internal inguinal ring so called, and the outward prolongation of this fascia, the infundibuliform fascia so called. This hiatus or internal inguinal ring transmits the spermatic artery, the spermatic veins, the vas deferens and its vessels, some nerves and lymphatics, and the fibrous cord remaining behind after the normal obliteration of the processus vaginalis. These structures are large in number, but small in size, and yet nature has been rather profligate in her dimensions, and has made the hiatus in the intraabdominal fascia more than ample for their transmission. This alone is to my mind sufficient to account for the greater frequency of oblique inguinal hernia, as compared to all others.

In addition there must not be forgotten abnormalities in the number and size of the vessels, particularly of the veins, which pass through the ring. I am also of the opinion that there must occur an alteration in the diameter of these structures, depending upon the greater or lesser amount of blood which passes through the vessels, depending upon the blood pressure in various states of health and disease, and upon the changing positions of the body; all of which tend to temporary dilatations, with a further weakening of the internal inguinal ring.

4. Mobility of the Peritoneum.—The parietal peritoneum is as a rule firmly attached to the underlying tissue in most parts of the abdomen, so that there is no unusual amount of redundancy. In the inguinal region, however, very probably in order to permit the alternating physiological distension and evacuation of the bladder, it is rather loosely attached. This loose attachment is of twofold significance. First, the peritoneum is very readily evaginated through the internal inguinal ring, and second, it accounts for the fact that oblique inguinal herniæ so readily attain large dimensions.

5. The usually erect position of the human race is also a factor inducive to the formation of hernia. I will, however, not enter into the details of this question, as it merely explains the greater frequency of hernia in man, as compared to many other mammals who by nature have an open processus vaginalis.

6. Hypoplasia of the Tissues.—Finally, I wish to call attention to a series of phenomena which are so closely interwoven with each other, and which merge so gradually one into another that their separation into simple factors is a matter of some difficulty. While composed of definite elements I have grouped them collectively under the heading of hypoplasia of the tissues.

It is important to remember that empty spaces never exist in the abdomen, on the contrary each crevice is completely filled out by the alternating shape of the abdominal contents. When a hollow viscus contracts and becomes smaller then either a neighboring viscus dilates and takes up the diminished space, or the muscles of the abdominal parietes contract and diminish the capacity of the

peritoneal cavity. It also requires a very carefully and well regulated mechanism in order to keep the viscera in position, and yet to allow a certain amount of mobility, in order to permit all the necessary physiological motions. Considerable discussions have taken place as to the forces, whose rôle it is to keep the viscera in position. Some authors assume that the main importance is to be attached to the fixation apparatus of the viscera, *i.e.* the so-called ligaments or mesenteries. Others deny at best a sufficient fixation of the viscera, and assert that the main reliance is to be placed upon the supporting forces, namely, the bones and muscles and fasciæ of the abdominal walls and pelvis. Others again ascribe a very important rôle to the atmospheric pressure exerted through the abdominal walls. And finally still others lay great stress upon the force of negative pressure exerted through the alternating contractions and relaxations of the diaphragm and other muscles of respiration. Personally I do not wish to take a positive stand in deciding the question, but it appears to me to be most probable that all these forces, and perhaps additional forces, have a rôle in the fixation of the viscera.

It is immaterial to us whether the main reliance in the fixation of the viscera is to be placed upon the mesenteric attachments or not, but it cannot be denied that these ligaments do really possess a certain inherent strength. That being the case it must also be conceded that this strength can and must be diminishable by atrophic processes of an acquired or congenital nature. The natural result will be a sagging or sinking of the attached viscera, which would constitute one variety of visceral ptosis.

It is furthermore immaterial to me whether the main reliance in the normal retention of the viscera is to be placed upon the supporting forces, but for the sake of argument it must be conceded that a certain amount of the retention of the viscera in a normal position is due to the support which they derive from the abdominal and pelvic muscles, fasciæ, and bones. Let us now assume that any one or more of these structures has been weakened, either by disease or by some atrophic process; then it must be also conceded that the viscera supported by them must sag to a lower level. This would constitute a second variety of visceral ptosis.

If this state is possible with a disturbance of one of the forces, how much more likely is it to happen when both forces, *i.e.* the fixative and the supporting forces, are disturbed. I am of the opinion that this is what actually happens in most instances, *i.e.* when there is a weakening of both forces, somewhat in the line of a hypoplasia of all the tissues which come into play. Incidentally I may add that this is perhaps an excellent way to account for the fact that it is not the blacksmith or hardworking laborer who most frequently acquires a hernia, but the ill-nourished man of sedentary habits.

An individual thus afflicted with a hypoplasia of the tissues presents in addition to other well-marked symptoms an unmistakable appearance. The supraumbilical region of the abdomen is usually sunken in, while the infraumbilical region is protuberant. Even different and distinct forms have been described, such as the "weiche Leiste" of the Germans, in which in the erect posture of the individual, both inguinal regions and just above and parallel with Poupart's ligament, are occupied by sausage shaped swellings. The "Pointe de hernie" of the French is similar in type, but appears only upon some, ever so slight, an exertion. The "ventre trilobe" in which the infraumbilical region of the abdomen is divided into three hillocks, two lateral and one median, is another example. There are still other varieties.

In all of the conditions just described the visceral ptosis may be looked upon as more or less permanent. There is, however, one other very important ptosis, which in contradistinction to the others is not due to any hypoplasia of the tissues and is only temporary. A very slight consideration of the anatomy of the parts will show at once that in the erect position all the viscera will bear a certain relation not only to each other, but also to the pelvis and parietes. This normal position will, however, be promptly altered when the position of the body is altered. All the mobile viscera will tend to be approximated to the pelvis and inguinal regions if the trunk is flexed upon the thigh, while the reverse takes place, for instance, in the Trendelenberg position. A similar condition takes place upon deep inspiration or exertion, as the diaphragm tends to become fixed in a much lower position, and thereby pushes and compresses the intestine into a lower level.

Assuming now the presence of any one of the conditions just described, we can very readily see how much easier it is for an individual thus afflicted to acquire an incipient hernia, or to acquire an increase of the hernia, after a beginning has already been made. It is beautifully illustrated, particularly, in that condition I have described as a temporary ptosis. Most individuals who ascribe their acquisition of a hernia to a particular time will usually be able to recollect a particular instant during which the conditions will conform to those just described.

Congenital Hernia.—Certain congenital malformations very frequently lead to congenital hernial sacs. It is not germane to the topic under discussion to discourse at great length upon the ways in which these malformations arise. Suffice it to say that in the normal descent of the testis into the scrotum, it is always either accompanied by, or according to some authorities even preceded by an outgrowth of the peritoneum, namely, the processus vaginalis. In the course of normal development this peritoneal process becomes shut off at the lower end, near the upper pole of the testis; the most distal portion remains and forms the tunica vaginalis. It also becomes shut off at the upper end flush with the peritoneum, while the intervening portion becomes obliterated and dwindles into a fibrous cord.

This shutting off process does not take place in some cases; it may fail to do so at either one, or at both ends, and failure of obliteration in the intervening portion may also occur. The abnormalities that may occur are manifold, however, only two are of interest to us at present.

1. The processus vaginalis does not become shut off at either end, nor does the intervening portion become obliterated. When this is the case we have a sac of peritoneum communicating freely with the peritoneal cavity above, while the distal portion contains the testis. This has received the somewhat ambiguous name of "congenital inguinal hernia." (Fig. 8.)

2. The processus vaginalis may become shut off

below, but it does not become shut off above, nor does the intervening portion become obliterated. In this case we also have an open sac communicating above with the peritoneal cavity, but it differs from the preceding variety in the fact that the distal portion of the sac does not harbor the testis. This

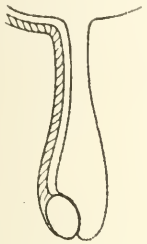

Fig. 8.—Diagram illustrating the sac of a congenital inguinal hernia.

form of anomaly has received the name of "hernia into the funicular process." (Fig. 9.)

It is stated very frequently that an individual afflicted with an undescended testis is particularly prone to the development of an inguinal hernia. I fully agree with this statement, but it must be clearly understood that the ready acquisition of a hernia in these cases is not due to the nondescent of the testis, but to the fact that in cases of nondescent of the testis the processus vaginalis fails to become shut off at either end; in other words, cases of undescended testes are accompanied by a sac of a so-called congenital inguinal hernia. These sacs are of various size and shape; their proximal end may be quite broad, so as to readily engage a piece of omentum or intestine; they vary in width, from one of extreme narrowness, so as to barely admit a probe, to that of a fully developed and wide sac.

In a previous chapter I have already pointed out how a hernial sac forms in its very beginning, and have traced its formation to full development and how a hernia develops after a sac has once been formed. In the class of cases under consideration here the entire process is abbreviated, because the sac is already fully formed at birth.

One further point must be emphasized, namely, that, while we call these cases, cases of congenital inguinal hernia, the hernia in reality is not congenital; all that is congenital is the sac. Hernial contents may find their way into the sac before or soon after birth, but not necessarily so; on the contrary sometimes they may not find their way into the sac until late in life, or never. This accounts for the fact that so frequently we obtain a history of the sudden development of a hernia during some strenuous exertion and a claim for damages is made, and yet when these cases are operated upon we find undoubted and incontrovertible evidence that the sac is of a congenital nature and not newly formed.

III. *Traumatic Hernia.*—I have now reached a point in my discussion which is beset with some danger. I also fear of being misunderstood because candor compels me to use a term which I am most anxious to avoid. When I originally set myself the task to write this paper my aim was to prove a fact, at which I arrived after many years of careful study, namely, that "traumatic hernia" does not exist. Traumatic hernia, however, does exist; in fact, it exists in so many different forms that their complete citation alone would exceed my limited time. Fortunately, they are so well known to you all that briefness on my part should not only be excusable but even welcome.

1. Herniæ which follow a clean laparotomy. In these the agent of the trauma is the surgeon's scalpel. Such herniæ may be due to various circumstances.

(*a*) Imperfect suturing. Formerly when most laparotomy incisions were sutured by through and through sutures, the resulting scar very frequently gave way and was followed by a hernia.

(*b*) Improper suture material. If, for instance, improperly prepared catgut, or catgut of insufficient strength has been used, it may become absorbed before firm union had taken place and is followed by a hernia.

(*c*) The sutures may have been tied too tightly, and may cut through the tissues, thus weakening the cicatrix with subsequent development of a hernia.

(*d*) Postoperative distension or vomiting may put such a strain on the sutures that the result will be similar to that described under the previous heading. Cases of postoperative subcutaneous prolapse occur in a similar manner.

2. Laparotomy incisions in which an infection has occurred. The fascial structures and muscles may slough, thus taking away one of the most important supporting elements of the abdominal wall.

3. Laparotomy incisions which require drainage are not infrequently followed by a hernia.

4. Certain cases of excision of the abdominal walls, for instance, for a tumor, in which only a very inadequate suture can be carried out, are very frequently followed by a hernia.

5. The abdominal parietes may be injured by being impinged upon objects, not necessarily, but still more or less sharp; for instance, by running or falling against a protruding object, for example, the handles of a wheelbarrow, or objects of a similar character, or by being gored by the horns of an animal, etc. The finaly result may differ widely, as it depends upon the nature and extent of the injury produced, viz.:

(*a*) If all the layers are torn a complete prolapse of some of the intraabdominal contents will very probably result.

(*b*) If the skin holds, on account of its greater elasticity, but all the deeper layers, including the peritoneum, are torn, a subcutaneous prolapse will more likely result.

(*c*) If all the layers of the abdominal parietes are

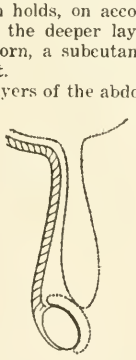

Fig. 9.—Diagram illustrating the sac of a hernia into the funicular process.

torn, but the peritoneum remains intact, a traumatic hernia will very probably result.

6. An individual may fall from a height; in falling there may occur involuntarily and reflexly such a contraction of the abdominal muscles, most frequently of the recti that they and their fascia are

completely torn through with a resulting hernia.

7. Penetrating or nonpenetrating injuries of the thorax, with injury of tne diaphragm are frequently followed by traumatic diaphragmatic herniæ.

These are only a few examples of traumatic hernia; doubtless many others can be cited, but these are sufficient to show what I mean by the words "traumatic hernia." It is self-evident also that they differ absolutely from "traumatic herniæ in the usually accepted meaning."

I have now described three different groups of hernial possibilities. Let us now see how far these come within the scope of the various Workmen's Compensation Laws. Granted that an injury within the meaning of the law has been fully established, there are to my mind only three possibilities.

1. The particular hernia was surely not caused by the particular injury. Into this class I would unhesitatingly place all the herniæ placed into group 2; namely, all those of a congenital malformation; because in these the hernial sac had existed long prior to the occurrence of the particular injury; all that could occur at that particular moment was the protrusion of the hernial contents, and I have already pointed out with sufficient emphasis that this is unimportant; the important part is the sac. Into this catagory belong also those herniæ of group 3, subclassified under 1, 2, 3, and 4 for obvious reasons.

2. The particular hernia was surely caused by the particular injury. Into this class I would unhesitatingly place all those herniæ of group 3, subclassified under 5, 6, and 7. I have now entirely accounted for group 2 and group 3; there remains only one more possibility, namely:

3. There is some doubt whether the particular hernia was caused by the particular injury. As group 2 and group 3 have been already accounted for, there belong into this catagory all that big class grouped under 1.

I have been very anxious to be candid and frank, not only with you but also with myself. As already stated previously, I have no particular case in mind; I have no pet theory to prove; it is entirely immaterial to me how the law is interpreted; I do not care one iota whether a workingman receives compensation or not; if anything, I have been particularly solicitious to give all the benefits of doubt to the injured person; but I am also firmly convinced that if only hammered at long enough justice will finally prevail, even in so abstract a question as the relation of trauma to hernia.

If we divest the question of the relationship of trauma to hernia of all its extraneous legal aspects, which do not interest us as physicians, there remain finally only one point, namely, that a particular injury should have produced a particular hernia. I lay no claim to a knowledge of the law, but it does not require much of a legal knowledge to understant that the relationship between injury and result must be firmly and clearly established beyond any doubt. For the sake of clear understanding I may be permitted to bring a few concrete examples.

1. Let us assume that an individual in perfect health slips on a banana peel and fractures his thigh. We have here an injury, a trauma, followed by a fracture of the femur; the relationship between the two is well established, and such a person would be entitled to all damages that the law may allow. Now let us assume that an individual suffering from locomotor ataxia fractures his femur in turning around in bed. We have here also an injury followed by a similar fracture of the femur, but the relationship is not established, the fracture is not due to the injury, but is due to the unusual fragility of the bones caused by the underlying locomotor ataxia. The question remains, should this second person be also entitled to similar damages.

2. The accident when an individual in perfect health fractures his humerus during the act of pitching a baseball again shows the relationship between trauma and result; but would this relationship be as fairly established if it could be proven that long before the advent of the injury this individual was suffering from a central sarcoma of the fractured humerus?

3. An individual in perfect health in loading a truck tears off the long head of the biceps; here we have a direct relationship between the trauma and the result; but how would this relationship be if it could be proven that the tendon involved was affected by tuberculosis long before the receipt of the injury?

I have brought forward these three examples to prove only one point, namely, that where an individual acquires a palpable and visible hernia in the course of his work, and if there was already present an impalpable and invisible hernia, or an open sac of congenital malformation, the relationship between the trauma and the result is altogether different than if it occurs in a perfectly healthy individual.

Let us now look at another phase of the subject. Based perhaps upon the ancient and discarded theory of the necessity of the presence of a rupture of the peritoneum in every hernia, there still exists in the minds of the lay people and with the advent of Workmen's Compensation Laws, also in the minds of the legal profession, an idea that something ruptured, something tore, and that the injury ot "that" particular something was the cause of the hernia. But you know, and I know, and the entire medical profession knows that such a pathology has never been found in the ordinary inguinal hernia. If only we can make this one point clear it would knock every support from under the claimants and their advocates.

The question may with propriety be asked, are there any definite criteria which characterize a traumatic hernia? The reply to this question is debatable from the viewpoint of the afflicted individual, and from the viewpoint of established medicine.

From the viewpoint of the patient every hernia which originated during his work is traumatic in nature, and in order to prove his contention the claimant adduces the following arguments. In parentheses I may add that the particular claim is made honestly and in perfect good faith. I exclude *eo ipso* from my arguments all those cases in which claims for indemnity are made by fraud. That such cases exist is amply proven by the records of the various compensation commissions throughout the world and by the files of a certain social-democratic paper in Germany, called "*der Töpfer*," in which directions are even given to prospective claimants, prior to the receipt of an alleged injury.

1. The patient who notices a swelling in either inguinal region usually sooner or later consults a physician. Upon inquiry, particularly if a claim is in view, he is frequently able to set a definite time for the appearance of the hernia, and not infrequently will be able to recollect some definite effort,

so called "überheben" of the German, or "strain" of the English language, during which the hernia first made its appearance. If my pathogenesis of an acquired hernia is correct it must be patent to everybody that the history as given by the patient is unreliable and not worthy of credit. It is most probable that the sac of this hernia has been long in formation and that though small in size it was present for a long time, only unnoticed by the patient. Most frequently the patient notices the hernia only when it has escaped through the external inguinal ring and has made a palpable swelling.

I might as well adduce here as a counter argument the fact, well known to every surgeon, that herniæ of recent date are frequently operated upon in adults, but in whom the operation discloses incontrovertible evidence that the sac is of a congenital origin.

2. In a majority of the cases the patient will also be able to certify that up to the moment of the alleged injury ("überheben" or "strain") there had never existed a hernia; he may even bring witnesses from amongst his fellow workers to that effect; but it is well known how easily such witnesses may be duped. Occasionally even a physician will testify that the patient had not been afflicted with a hernia prior to the receipt of the assumed injury. Even this apparently valid testimony is of very questionable value, as it is a well-known fact that even physicians on very careful examination can only testify to the presence of hernial contents. If the sac is empty at the time of the examination and persistently stays empty, he cannot testify to the absence of a hernia. In other words it only reiterates the well-known axiom in medicine that a positive proof is absolute, but a negative proof is no proof at all. This is also beautifully illustrated in those cases already referred to in which an individual is operated upon late in life for a hernia of short duration and yet the operation reveals a sac of congenital formation.

3. The sudden acquisition of pain in the inguinal region, which had not existed previously, is frequently brought forward by claimants as an argument in favor of the traumatic origin of the hernia. This is a very unreliable phenomenon for several reasons: first, because pain is too subjective a symptom; second, because herniæ of small or large size may exist for a long time without any pain at all; and third, because I am convinced that pain in a hernia is due only to stretching of the sac, consequent to a sudden descent of more hernial contents than it has hitherto accommodated. If anything, it may even be argued from this phenomenon that the hernia is old and not at all of recent standing.

4. Strangulation of a hernia, with its attendant train of symptoms, is occasionally used by claimants to verify a claim that the hernia is of traumatic origin. Hardly any importance should be attached to such an argument. It is a well-known fact that strangulation may occur at any time during the life history of a hernia. On the contrary, the very point of strangulation may just as appropriately be used as a counter-argument, because in many instances the strangulation is induced only by the sudden descent of more hernial contents than the sac has hitherto accommodated.

From the viewpoint of the surgeon an open operation and an open operation only can decide the question of the existence of a traumatic hernia with certainty. In recent cases all evidences of a trauma, particularly that of a hematoma, or at least traces of it in the form of unabsorbed blood, can readily be seen. There should be also evident tears or lacerations in the abdominal parietes with separation of the edges. In older cases the effused blood will very probably have all been absorbed, but careful examination of the parts will, even after the lapse of years, show the effects of the trauma.

I make this statement with a positive degree of assurance, as I have had occasion to operate upon a number of cases of a subvariety of "traumatic" inguinal hernia, and have never failed to find evidences of the trauma beyond any question of doubt. I refer to cases of socalled "artificial hernia."

Cases of this nature usually affect Russian Jews, and careful questioning will usually elicit the fact that they had these herniæ made to order in order to escape military conscription. The history of the *modus operandi* is approximately the following: The willing victim is usually blindfolded so that he does not even see the "operator," and is placed upon the floor in the dorsal position. The operator then invaginates his finger through the scrotum into the external inguinal ring; directly after this the patient experiences violent pain in the inguinal region (some even faint). Thereafter the patient is ordered a snuff and also an emetic, usually an emulsion of yeast in water. The ensuing sneezing and vomiting is soon followed by the appearance of a small hernia.

At operation in these cases there is only occasionally found a laceration of the aponeurosis of the external oblique; but with unfailing regularity a tear with separation of the edges of that part of the transversalis fascia covering Hesselbach's triangle.

Now, these are true traumatic herniæ, but they are something totally different from those for which claims are usually made.

In the preceding it has been my aim to analyze and clarify the subject. In conclusion it is somewhat disagreeable to me to find myself compelled to use a term which may again tend to befog the subject, but I find it unavoidable. It would be, perhaps, wise to divide all herniæ from this viewpoint into two classes, namely, "herniæ caused by effort" and "herniæ caused by trauma." The principal difference between the two is that "herniæ caused by effort" always occur in certain definite locations, locations predestined to the formation of a hernia by a certain definite weakness in the intraabdominal fascia caused by the passage of a blood vessel; while the true "traumatic hernia" may occur in any part of the abdomen, usually, however, not in any predestined place. Of course, a traumatic inguinal hernia may occur, if, for instance, a trauma would tear the transversalis fascia just at the internal inguinal ring; but the chances for its doing so are so remote and so infinitesimal as to be barely worth while considering. My reasons for not wishing to raise this question are that it would again throw the entire question open to judicial interpretation as to whether the word "effort" comes within the scope of the various Workmen's Compensation Laws. If the question is decided in the affirmative then it should be advocated to award compensation in every case of hernia that may occur in a workingman, and that would evidently be preposterous.

It does not require any arguments on my part to convince you as medical men of the correctness of my attitude. Unfortunately, however, the problem is a more complicated one, as it concerns not

only medical men but also the employer, the employee, Workingmen's Compensation Commissions, the legal profession, judges and juries. A review of unbiased medical opinions is hardly called for because it is practically unanimous, and in all essentials agrees with the stand I have taken. A review of legal decisions upon the subject would be very interesting, but is evidently beyond my sphere. However, it may interest you to know that most of the opinions rendered by the Workmen's Compensation Commissions of various States have given their decisions in accordance with the views as stated herein, or have sidestepped them, fearing to give a definite decision by compromising the case. It is only when a particular case is tried in open court before a jury, even in the presence of "interested" expert witnesses, that the laws of nature miscarry and faulty decisions are rendered. Witness one of the most recent decisions in the State of Washington in the case of Zappala vs. The Industrial Insurance Commission. The language of the final decision of the Supreme Court of the State of Washington reads as follows:

" 'Sustaining of an injury while using extreme muscular effort in pushing a heavily-loaded truck is as much within the meaning of accident even as though the injury was the result of a fall or the breaking of the truck. To hold with the commission that if a machine breaks, any resulting injury to a workman is within the act, but if the man breaks, any resulting injury is not within the act, is too refined to come within the policy of the act as announced by the Legislature in its adoption and the language of the court in its interpretation.' "

Conclusions.—1. Traumatic hernia is exceedingly rare.

2. Traumatic hernia may occur in any part of the abdomen, but usually not at the site of the normal hernial openings.

3. Nontraumatic hernia is frequent and occurs at certain definite and predestined locations caused by weak areas in the intraabdominal fascia.

4. Workmen's Compensation Commissions are not and cannot be acquainted with all the facts relating to hernia. This is evidently the sphere of the medical profession; and Workmen's Compensation Commissions should be required to place implicit reliance in these matters upon the decisions of established medicine.

5. In cases of appeal from the decision of the commission, all the medical part of the testimony should be given by experts of the court's selection and not of the selection of the claimant or defendant.

A NEW NON-OPERATIVE TREATMENT OF DISEASE OF THE ACCESSORY SINUSES OF THE NOSE.

PRELIMINARY REPORT.

By LEWIS A. COFFIN, M.D.,

NEW YORK.

Since the grip epidemic of 1889, disease of the accessory sinuses of the nose has held the center of the stage in rhinological thought, discussion, literature, and practice. Outside of the very acute cases, the most that has been done for the patient suffering from an empyema of any or all of the sinuses has been along surgical lines. The extent of surgical procedure has depended not alone upon the extent of the disease, but upon the ability, technique, and mind of the operator in charge of the case. All have recognized the fact that in many unattended cases of disease of these cavities there exists a marked potential of danger to life through cerebral involvement, to the eye through involvement of the optic nerve, and always great distress to the patient, if not on account of the frequent accompaniment of pain, certainly on account of the ever present and annoying nasal discharge.

Operation is done frequently to the extent only of giving free drainage to the diseased cavity which relieves the pain and greatly reduces the potential of danger. More radical operation having for its object not only the accomplishment of the above results, but the stoppage of the distressing discharge is frequently done.

The most radical and I believe the most effective is the so-called Radical Killian Operation for the Relief of Empyema of Frontal, Ethmoidal and Sphenoidal Sinuses.

This operation, when well done, as a rule results in a complete cure of the disease. The disadvantages of the operation are that certain more or less important parts of the nose are destroyed, and there results a more or less scarring and deformity of the face. Certainly any non-operative treatment which bids fair to eradicate the disease of these obscure cavities in the majority of cases must be a most welcome addition to our means of aid to those suffering from this troublesome disease.

I take pleasure in describing a method of treatment which I believe gives greater promise in these cases than any other so far used.

Suction, negative pressure, or vacuum cleaning processes have been in vogue and increasing in practice for the last several years. The writer one year ago before the American Laryngological Association described and recommended this treatment as applied to the relief of sinusitis in children.

Some two or three months ago having "sucked" some of the pus from the accessory sinuses of a nose, I inoculated a culture tube with secretion taken from the nose after several applications of the negative pressure. The pathologist told me that it was almost impossible to separate out and grow the pathogenic organism, as there were present so many air germs, and suggested that probably this was due to the fact that there was such an unusual inrush of air into these partially vacuumized cavities when the nasal tip of the suction apparatus was removed from the nose. This seemed reasonable, and it occurred to me that we might make use of this Nature's abhorrence of a vacuum for the introduction of remedial measures into the sinuses. I had constructed apparatus such that I could at will produce in the nose and its accessory cavities either a negative or positive pressure and such that I could change from one to the other immediately. By means of the positive pressure obtained from an oxygen tank I was able to throw medicated vapor well into these cavities. That the current of oxygen enters the cavities is proved by this fact; after all the pus or mucus that can be obtained by the suction process has been taken from the cavities, and the nasal chambers proper have been thoroughly cleaned, one may by using for a time alternating suction and pressure currents obtain much more pus, in fact so much at times as to astound one. The pressure current seems to sweep it off the walls of the cavities as it were and into such position that the suction current can pick it up.

Whereas my almost home-made apparatus works perfectly, I am having it refined and perfected by the instrument makers. When the perfected instrument is in hand I shall describe it, outline more fully the technique, the various remedial measures used, and report cases.

CONTRIBUTION TO THE STUDY OF CHRONIC APPENDICITIS.

By CARLO SAVINI, M.D.,

NEW YORK.

Chronic appendicitis is clinically a well defined pathological entity, but its lesions are anatomically variously interpreted.

It is very important to reach a conclusion in regard to the nature of these anatomical findings, as the knowledge of the pathogenesis of appendicitis in general is founded upon the study of the anatomical lesions of the chronic disease.

In necrotic appendicitis the destruction of the appendicular layers proceeds so rapidly that we cannot observe the sequence of the pathological changes; but in chronic appendicitis the changes occur more slowly, and if we direct our attention to numerous specimens, we can reconstruct the process and almost follow it from its beginning to its end.

No conclusion can be drawn by the examination of only one section or of only one specimen. Numerous sections of the same specimen and numerous specimens should be observed and compared to obtain a correct idea of how the lesions occur. It will be then evident that these lesions although different are all due to a similar cause, and that in their essence they should be considered as processes of repair.

Before proceeding to the analysis of these lesions it is necessary to make a few general remarks.

The vermiform appendix was formerly considered to be an involutive organ. Now it is proved that the appendix is not involutive, either phylogenetically or ontologically. It was also said that the appendix undergoes a process of regression during the life of the individual. This assertion has not been proven to my satisfaction. In my own experience I found that, excluding the operations for appendicitis, in five hundred laparotomies performed for various other diseases only one hundred and twenty-four times was it necessary to remove the appendix. In the remaining seventy-five per cent. of the cases, the appendix was apparently normal and well developed, irrespective of the sex and of the age of the patient.

On the assumption that the appendix is involutive and regressive, small lesions found in its mucosa have been disregarded and often derided and considered almost physiological.

The appendix has been likened to the tonsils and has been called the tonsil of the intestine. This similarity has given to the lymphoid nodules of the appendix the first importance in the pathogenesis of the disease. But the lymph nodes or follicles are present and abundant not only in the appendix, but in all the intestinal tract. They are certainly larger in the small intestine and there is no reason why the appendix should be singled out for the comparison.
